CANADIAN PLANT DISEASE SURVEY

- DISEASE HIGHLIGHTS

SOCIÉTÉ CANADIENNE DE PHYTOPATHOLOGIE / INVENTAIRE DES MALADIES DES PLANTES AU CANADA - APERÇU DES MALADIES

The Society recognizes the continuing need for publication of plant disease surveys which benefit both federal and provincial agencies in planning appropriate research for the control of plant diseases. The reports you contribute are important to document plant pathology in Canada.

The *Canadian Plant Disease Survey* is a periodical of information and record on the occurrence and severity of plant diseases in Canada and on the assessment of losses from disease.

Authors who have traditionally published scientific notes in the *Canadian Plant Disease Survey* are encouraged to submit this material to the scientific journal of their choice, such as the *Canadian Journal of Plant Pathology* and *Phytoprotection.*

L'Inventaire des maladies des plantes au Canada est un périodique d'information sur la fréquence des maladies des plantes au Canada, leur gravité, et les pertes qu'elles occasionnent.

On encourage les auteurs, qui traditionnellement publiaient des articles scientifiques dans l'Inventaire des maladies des plantes au Canada, à soumettre dorénavant leurs textes au journal scientifique de leur choix, par exemple, la *Revue canadienne de phytopathologie* et *Phytoprotection.*

CROP: Commercial crops - Diagnostic Laboratory Report

LOCATION: British Columbia

NAME AND AGENCY:
Vippen Joshi, P.Ag.
Plant Diagnostic Pathologist, BC Ministry of Agriculture, Food and Fisheries
Abbotsford Agriculture Centre, 1767 Angus Campbell Road, Abbotsford, BC V3G 2M3

TITLE: DISEASES DIAGNOSED ON COMMERCIAL CROPS SUBMITTED TO THE BCMAFF PLANT DIAGNOSTIC LABORATORY IN 2000.

METHODS: The BCMAFF Plant Diagnostic Laboratory provides diagnosis and control recommendations for diseases and disorders of commercial agricultural crops grown in British Columbia. The following data reflect samples submitted to the laboratory by the Ministry extension staff, growers, agribusinesses, parks boards, and master gardeners. Diagnoses were accomplished by microscopic examination, culturing onto artificial media, biochemical identification of bacteria using BIOLOG® and serological testing for viruses and bacteria with micro-well and membrane based Enzyme-Linked Immunosorbent Assay (ELISA). Some specimens were forwarded to other laboratories for identification or confirmation of the diagnosis. The lab does not do soil nutrient, tissue nutrient or chemical residue analyses.

RESULTS AND COMMENTS: Summaries of the diseases and their causal agents diagnosed on commercial crops are presented in Tables 1-9 by crop category. The total number of submissions for each crop category is listed at the bottom of each table. Problems not listed include: no disease and abiotic problems such as nutritional stress, pH imbalance, water stress, poor sample, physiological response to growing conditions, environmental and chemical damage, insect-related injury and damage where no conclusive causal factor was identified.

Table 1. Summary of diseases diagnosed on **field crop** samples submitted to the BCMAFF Plant Diagnostic Laboratory in 2000.

Crop: Commercial Crops - Diagnostic Laboratory Report

Location: Alberta

Name and Agency:
K. Basu , S. Mathur and B.J. Penner
Brooks Diagnostics Limited
Crop Diversification Centre South, Brooks, Alberta, Canada T1R 1C5

Title: CROP DISEASE SUMMARY FOR SAMPLES SUBMITTED TO BROOKS DIAGNOSTICS LTD. FROM ALBERTA IN 2000

Methods: Brooks Diagnostics Limited (BDL), a private plant health clinic, provided diagnosis of diseases on commercial crops and other plants submitted by farmers, extension specialists, scientists, agribusinesses, market gardeners, florists, greenhouse growers, landscaping companies, municipal parks departments staff, nurseries, golf courses, and the general public from January 1 to August 30, 2000. The company closed its doors in September after being in business for seven years.

Results: Disease identifications from various crop categories are summarized in Tables 1-10, and are organized according to the region of submission. BDL also received samples with insect damage and from regions other than Alberta. These data are not included in this report.

CROP: Commercial crops - Diagnostic Laboratory Report

LOCATION: Saskatchewan

NAME AND AGENCY:

G. Holzgang[1] and P. Pearse[2]

[1] Crop Protection Laboratory, Saskatchewan Agriculture and Food, 346 McDonald St., Regina, Saskatchewan S4N 6P6

[2]Saskatchewan Agriculture and Food, Sustainable Production Branch, 3085 Albert St., Regina, Saskatchewan S4S 0B1

TITLE: DISEASES DIAGNOSED ON CROP SAMPLES SUBMITTED TO THE SASKATCHEWAN AGRICULTURE AND FOOD CROP PROTECTION LABORATORY IN 2000.

METHODS: Saskatchewan Agriculture and Food's (SAF) Crop Protection Laboratory provides diagnostic services and recommendations for crop health problems to the agricultural industry. Services include disease, insect and weed identification and testing of weeds for herbicide resistance. Samples are submitted to the Crop Protection Laboratory by SAF Extension Agrologists, growers, agribusiness and home gardeners. Disease diagnosis is accomplished by microscopic examination, culturing on artificial media, ELISA testing and BIOLOG™.

RESULTS: In 2000 the Crop Protection Laboratory received 1054 samples (April 1 - November 2, 2000) of which 75% were for disease diagnosis (39% of these were for Dutch elm disease). Other than Dutch elm disease, 34% cereals, 3% forages, 2% fruit, 10% oilseeds, 37% special crops, 2% vegetables and 10% woody ornamentals, herbaceous ornamentals, turf and greenhouse comprised the remainder. Summaries of diseases/causal agents diagnosed on crop samples submitted to the Crop Protection Laboratory in 2000 are presented in Tables 1-8 by crop category.

Table 1. Summary of plant diseases diagnosed on **cereal crops** submitted to the SAF Crop Protection Laboratory in 2000.

CROP	DISEASE/CAUSAL AGENT	NO. OF SAMPLES
Barley	Net blotch/*Pyrenophora teres*	6
	Common root rot/*Cochliobolus sativus, Fusarium* spp.	3

TITLE: 2000 MANITOBA CROP DIAGNOSTIC CENTRE LABORATORY SUBMISSIONS

METHODS: The Manitoba Agriculture and Food Crop Diagnostic Centre provides diagnoses and control recommendations for disease problems of agricultural crops and ornamentals. Samples are submitted by Manitoba Agriculture and Food extension staff, farmers, agri-business, and the general public. Diagnosis is based on visual examination for symptoms and culturing onto artificial media.

RESULTS: Summaries of diseases diagnosed on plants in different crop categories are presented in Tables 1-10.

Table 1. Summary of diseases diagnosed on **cereal crops** submitted to the Manitoba Agriculture and Food Crop Diagnostic Centre in 2000.

CROP	SYMPTOM/ DISEASE	CAUSAL AGENT	NO. OF SAMPLES

CROP: Diagnostic Laboratory Report - Commercial Crops

LOCATION: Québec

NAME AND AGENCY:
G. Gilbert, M. Lacroix and D. Hamel
Ministère de l'Agriculture, des Pêcheries et de l'Alimentation du Québec (MAPAQ),
Complexe scientifique, 2700, rue Einstein - D.1.200h, Sainte-Foy, Québec G1P 3W8

TITLE: DISEASES DIAGNOSED ON COMMERCIAL CROPS SUBMITTED TO THE MAPAQ DIAGNOSTIC LABORATORY IN 2000

METHODS: The objective of the MAPAQ diagnostic laboratory is to provide diagnosis and control recommendations for disease problems of commercial crops. The following data reflect diagnoses of samples submitted to the laboratory by extension staff of MAPAQ, the "Régie des assurances agricoles du Québec", the "Institut québécois du développement de l'horticulture ornementale" and by the agricultural industry. Diagnosis is based on visual examination of symptoms and on the use of various laboratory tests to detect and to identify pathogens. The following tests are used in the laboratory; for nematodes, isolation with the Baermann funnel and microscope examination; for fungi, isolation on artificial media, microscope examination and pathogenicity testing; for bacteria, isolation on artificial media, classical biochemical tests including API-20E and Biolog®, ELISA and PCR tests; for phytoplasmas, PCR tests and for viruses, ELISA tests.

RESULTS AND COMMENTS: The distribution of crop samples was: vegetable crops 25.9%, greenhouse vegetables 11.6%, storage vegetables 3.8%, small fruit 26.5%, apple trees 2.5%, perennials and woody ornamentals 7.0%, greenhouse ornamentals 13.3%, cereal crops 3.5%, herbs 1.3% and other crops 4.3%. Problems not listed include insect related injury, pathogen detection in substrates and asymptomatic plants, damage where no conclusive disease-causing organism was identified and seed problems.

ACKNOWLEDGEMENT: The authors gratefully thank Carolle Fortin, Chantal Malenfant, Mario Tésolin and Lise Vézina for technical assistance.

Table 1. Summary of **vegetable field crop** diseases diagnosed by the MAPAQ diagnostic laboratory in 2000.

TITRE / TITLE : **SURVOL DES MALADIES DES CÉRÉALES PRÉSENTES AU QUÉBEC EN 2000**

INTRODUCTION ET MÉTHODES : La majorité des essais de céréales de printemps du réseau d'enregistrement et recommandation du Québec ont été visitée une fois entre la mi-juillet et la mi-août dans le but de noter l'incidence des maladies des parties aériennes. On a aussi prélevé des racines et des épis dans des champs d'orge et de blé à divers endroits au Québec afin d'étudier les pourritures racinaires et d'évaluer le taux d'infection des épis causée par les *Fusarium* spp. En général, les plantes examinées lors des visites des essais étaient au stade de développement laiteux moyen et celles dont les épis ont été prélevés, étaient au stade pâteux moyen. Pour les pourritures racinaires, les prélèvements ont été fait entre 2 et 6 semaines après le semis et on a isolé les agents pathogènes à l'aide de milieux sélectifs.

RÉSULTATS et COMMENTAIRES : L'année 2000 se caractérise par un printemps difficile (température et précipitations) ce qui a occasionné un retard dans les semis dans la plupart des régions. La saison a également été plus fraîche et pluvieuse dans le centre et dans sud-ouest du Québec, alors qu'à l'est de La Pocatière les premières pluies après le semis ont été suivies d'une longue sécheresse.

Bien que la saison 2000 ait été beaucoup plus pluvieuse que la normale dans les régions visitées, la fusariose de l'épi (*Fusarium graminearum* principalement) a eu une incidence relativement faible : le pourcentage d'épillets fusariés était de 3,6 % chez le blé (région de Montréal : 4,0%; région Centre-Québec : 2,1%) et de 5,5 % chez l'orge (région de Montréal : 6,1%; région Centre-Québec 5,5%). On peut peut-être expliquer ce résultat par les températures fraîches de la saison qui ont dû favoriser le développement d'espèces fongiques mieux adaptés au climat frais que le *F. graminearum*.

Chez l'avoine, la tache ovoïde (*Stagonospora avenae*) était la maladie foliaire la plus répandue. Son incidence a été plus marquée à Normandin que dans les autres stations où l'intensité des symptômes était plutôt moyenne. La rouille couronnée (*Puccinica coronata*) était assez intense à Sainte-Anne-de-Bellevue dans le sud-ouest de la province, comme c'est souvent le cas. Elle était présente aussi à La Pocatière, mais à un degré moindre. Le virus de la jaunisse nanisante de l'orge (VJNO) a touché toutes les régions du Québec, bien que faiblement dans la plupart des cas.

Chez le blé, la tache auréolée (*Drechslera tritici-repentis*) et la tache causée par *Phaeospheria nodorum*, appelée communément septoriose, ont été encore cette année les maladies foliaires les plus répandues avec un niveau d'infection modéré. La rouille des feuilles (*Puccinia recondita*) a été observée dans presque toutes les régions du Québec et son incidence a été estimée à moyenne; ce qui est plus élevée qu'à l'habitude. Un autre fait marquant, le VJNO s'est manifesté dans toutes les régions. Les symptômes ont même pu être notés à l'Acadie, Princeville et Hébertville. On estime des dommages dans certains

champs allant de 5 à 10 %. Quant à l'oïdium, causé par *Erysiphe graminis*, il est apparu de façon sporadique à l'état de trace, mais à Princeville l'intensité des symptômes était plus élevée. Le piétin brun (*Pythium* spp.) a été la maladie racinaire dominante de la saison. On a aussi observé du piétin échaudage (*Gaeumannomyces graminis*) à la station de Pintendre.

Chez l'orge, la rayure réticulée (*Drechslera teres*) était prédominante partout au Québec. La rouille des feuilles (*Puccinia hordei*), quant à elle, a eu une incidence faible à moyenne là où elle a été observée, soit aux stations situées dans la vallée du Saint-Laurent. L'oïdium qui est une maladie peu courante au Québec, n'a en effet été observée qu'à La Pocatière, la station visitée la plus à l'est. Pour certains cultivars, l'infection a même atteint la feuille étendard. Le VJNO, tout comme chez le blé, a été très présent cette année. Il a même été observé en Gaspésie, dans la vallée de la Matapédia. La rhynchosporiose (*Rhynchosporium secalis*) que l'on retrouve certaines années était quasi absente en 2000. Quant aux maladies racinaires, le piétin brun était dominant tout comme chez le blé, mais a causé des pertes plus graves. On pense que dans certains champs, des pertes excédant 50 % étaient dues en grande partie aux *Pythium*.

TITLE / TITRE: FUSARIUM HEAD BLIGHT OF BARLEY IN SASKATCHEWAN IN 2000

INTRODUCTION AND METHODS: The incidence and severity of fusarium head blight (FHB) were assessed in 42 2-row and 21 6-row barley fields from 18 crop districts (CD) in Saskatchewan. Heads from 50 plants, at milk to dough stages, were collected randomly from each field and sent to the Crop Protection Laboratory in Regina for disease assessment, and pathogen isolation and identification. An FHB index (percent number of heads affected x mean severity of infection/100) was determined for each field. An average FHB index for infected fields in each CD, and for CDs grouped by soil zone (Zone I=Brown, Zone II=Dark Brown and Zone III=Black/Grey soils) was calculated. Kernels from heads with symptoms were surface sterilized in 10% Javex solution for 1 minute and plated on potato dextrose agar for identification of *Fusarium* spp.

RESULTS AND COMMENTS: Overall, 75% of barley fields surveyed were affected by FHB, a higher percentage than in 1999 (65%) or 1998 (59%) (Table 1; Fernandez et al. 1999; 2000). However, the mean FHB index was lower in 2000 (0.6%) than in 1999 (1.0%) or 1998 (1.4%). In 2000, the incidence of FHB was lower for 2-row (67%) than 6-row (90%) barley (Table 1). Conversely, the average FHB index was higher for 2-row (0.9%) than 6-row (0.2%) barley. This is similar to results from the 1999 survey. The mean FHB index was highest in crop districts 1B, 2B (south-east) and 5A (east-central). Individual fields with the highest FHB index (1.4% to 7.8%) were found in CDs 1B, 2B, 5A and 9B (north-west). The proportion of affected fields and their average FHB index was lowest in Zone I (south-west).

Fusarium sporotrichioides was isolated from the greatest number of fields, followed by *F. poae* and *F. avenaceum* (Table 1). *Fusarium culmorum* and *F. graminearum* were present in few fields. *F. sporotrichioides* was more prevalent in 2000 (77% of fields) than in 1999 (40%) or 1998 (22%).

We gratefully acknowledge the participation of Saskatchewan Agriculture and Food extension agrologists in this survey, and financial support by the Agriculture Development Fund.

TITLE / TITRE: SURVEY FOR LEAF SPOT DISEASES OF BARLEY IN MANITOBA IN 2000

INTRODUCTION AND METHODS: Foliar diseases of barley in Manitoba were assessed by surveying 78 farm fields (21 two-row, 57 six-row) from July 24 to August 3 when most crops were at the milky to soft dough stage of growth (ZGS 72-89). Fields were sampled at regular intervals along survey routes, depending on availability. Disease severity was recorded by sampling approximately 10 plants along a diamond-shaped transect of about 50 m per side, beginning near the field edge. Severity ratings were taken on both the upper (flag and penultimate leaves) and lower leaf canopies, using a six-category scale: 0 or nil (no visible symptoms); trace (<1% leaf area affected); very slight (1-5%); slight (6-15%); moderate (16-40%); and severe (41-100%). Infected leaves with typical symptoms were collected at each site, dried and stored in paper envelopes. Surface-sterilized pieces of infected leaf tissue were placed in moist chambers for 3-5 days to identify the causal agent(s) and determine the disease(s) present.

RESULTS AND COMMENTS: Conditions in Manitoba in 2000 were relatively dry and cool early in the growing season (to early June) but then became warmer and considerably wetter to mid September, by which time most barley had been harvested. Leaf spot development was therefore somewhat delayed and in most cases did not become overly damaging, particularly as many crops were seeded early. As noted in former reports, the field history, i.e., presence or absence of barley stubble from the previous year, appeared to have the most influence on the level of leaf spotting observed.

Leaf spots were observed in the upper and/or lower leaf canopies of all barley fields surveyed. Disease severities in the upper canopy were nil, trace or very slight in 31% of fields, slight in 51%, moderate in 13%, and severe or leaves senescent in 5%. Respective severity categories in the lower canopy were tabulated as 4%, 41%, 23%, and 32%. These results are almost identical to those found in 1999. On this basis, foliar diseases in barley caused relatively little damage in 2000; on average, grain yield losses were likely in the range of 2-3%.

Pyrenophora teres and *Cochliobolus sativus*, causal agents of net blotch and spot blotch, respectively, were most frequently isolated from infected leaf tissue, and were responsible for most of the leaf spotting recorded (Table 1). *Septoria passerinii* (speckled leaf blotch) was recovered from about 1/4 of the fields, but caused relatively little of the damage observed. *Rhynchosporium secalis* (scald) was detected in two fields, and *Stagonospora nodorum* was found in 6 fields, causing less than 2% of the damage. The predominance of *P. teres* and *C. sativus* as leaf spot pathogens of barley in Manitoba in 2000 was typical of most years.

Table 1. Prevalence and isolation frequency of leaf spot pathogens of barley in Manitoba in 2000

PATHOGEN	PREVALENCE (% OF FIELDS)	DAMAGE (% OF ISOLATIONS)
Pyrenophora teres	84.6	52.4
Cochliobolus sativus	76.9	40.3
Septoria passerinii	25.6	5.4
Stagonospora nodorum	7.7	1.6
Rhynchosporium secalis	2.6	0.3

TITLE / TITRE: FUSARIUM HEAD BLIGHT OF BARLEY IN MANITOBA AND SOUTH-EASTERN SASKATCHEWAN IN 2000

INTRODUCTION AND METHODS: A total of 78 barley fields (21 two-row, 57 six-row) in southern Manitoba and south-eastern Saskatchewan were surveyed for the presence of fusarium head blight (FHB) between July 24 and August 3, 2000. Fields were selected randomly along the survey routes. FHB incidence (the percentage of heads with typical symptoms) in each field was assessed by sampling 80-100 spikes at 3 locations for disease. FHB severity (the average affected proportion of symptomatic heads) was estimated visually in the field. Thirty heads with FHB symptoms were collected at each field site, placed in plastic bags, and subsequently frozen. A total of 50 kernels, discoloured (putatively infected) whenever possible, and/or normal in appearance to make up the remainder, were removed from five heads per location. The kernels were surface sterilized in 0.3% NaOCl and plated onto potato dextrose agar to quantify and identify *Fusarium* spp. on the seed.

RESULTS AND COMMENTS: Conditions initially were unfavourable (cool and little precipitation) for development of FHB in Manitoba in 2000, but frequent rains beginning in mid-June, subsequently led to widespread and sometimes severe development of the disease. Fusarium head blight was found in 77 of 78 fields surveyed. Average incidence of FHB in two-row crops was 20% (range 6 - 83%) and severity also averaged 20% (range 1 - 66%); in six-row crops incidence was 33% (range 0 - 72%) and severity 16% (range 0 - 38%). The 2-row data are skewed somewhat as a result of very high incidence and severity values in one two-row field that was badly lodged. The resulting average FHB Index (incidence X severity / 100) was 3.9% (range 0.3 - 55%) for two-row and 5.4% (range 0 - 38%) in six-row barley. Based on these levels of incidence and severity, FHB was estimated to have caused yield losses averaging about 2% in barley in 2000, in the region surveyed. A comparison of FHB levels in the 8 south-eastern Saskatchewan barley fields surveyed with those from Manitoba, indicated considerably lower values for average incidence, severity and FHB Index (FHBI) in Saskatchewan (SK - incidence 12%, severity 6%, FHBI 0.7%; MB - incidence 32%, severity 17%, FHBI 5.5%). The *Fusarium* species isolated from kernels are shown in Table 1. As in the past several years, *F. graminearum* was the predominant pathogenic species. Levels of *F. graminearum* were lower, and those of *F. poae* and *F. avenaceum* higher, in south-eastern Saskatchewan compared to Manitoba.

Table 1. *Fusarium* spp. isolated from barley kernels in Manitoba and S.E. Saskatchewan in 2000.

***Fusarium* spp.**	**PERCENT OF FIELDS**		**PERCENT OF KERNELS**	
	MB	**MB**	**MB**	**SK**
F. graminearum	92.1	75	93	59.9

TITLE / TITRE: BARLEY YELLOW DWARF OF BARLEY IN EASTERN CANADA IN 2000

INTRODUCTION AND METHODS: In Quebec, barley yellow dwarf (BYD) was moderately abundant in the Lac St-Jean area and more damaging in the Matapedia valley. On the Central Experimental Farm (Ottawa ON), BYDV infection was considered to be the most severe in ten years. This article reports cultivar responses in barley to the BYD epidemic at the Central Experimental Farm.

Forty-nine barley cultivars or advanced breeding lines from Eastern Canada were seeded on May 31, 2000 at the Central Experimental Farm in a randomized complete block design with four replications for screening for reactions to fusarium head blight. The seeding rate was 22 seeds m^{-2}. Each experimental plot consisted of two 1.5-m rows with a row spacing of 15 cm. When leaves of some seedlings turned yellow between the veins, BYDV infection was suspected. On July 19 all of the experimental plots were rated on a scale of 0 to 9 with 0 being no leaf chlorosis and 9 being severe leaf chlorosis. To confirm the presence of BYDV, leaf samples of three cultivars (ACCA, AC Legend, and AC Maple) were collected on August 1 for an ELISA test for the PAV strain of barley yellow dwarf virus.

RESULTS AND COMMENTS: The ELISA test showed that the optical densities of ACCA leaf samples (0.040 and 0.084) were lower than those of AC Maple (0.087 and 0.266) and AC Legend (0.161 and 0.188) leaf samples. The leaf samples were collected from 2-month-old plants, thus considerable force might be required to extract the virus from these old and lignified tissues. We could have obtained more virus from these samples if they had been ground several times. The results suggest the presence of a significant amount of BYDV in AC Maple and AC Legend. The 49 barleys differed in reactions to BYD with ACCA being most resistant. ACCA carries the BYDV resistance gene *Yd2*. On average, two-row cultivars were more susceptible to BYDV than six-row cultivars (2.54 vs. 1.94, $P<0.05$). Bright yellow leaf chlorosis was also observed in the seed multiplication plots at the Central Experimental Farm. The ratings of leaf chlorosis for the 13 barleys in the multiplication plots were as follows: AC Klinck 1, AB186-3 2, Morrison 2, AC Alberte 4, AC Hamilton 4, AC Parkhill 4, AC Stephen 4, AB214-2 4, OBS4181-43 4, AC Legend 5, OBS4840-1 5, OBS4065-157 5, and AC Maple 6.

TITLE / TITRE: LEAF DISEASES OF BARLEY AND OAT IN SASKATCHEWAN IN 2000

INTRODUCTION AND METHODS: A survey of leaf diseases of barley and oat was conducted in fields randomly selected from most crop districts (CD) in Saskatchewan. Ten flag and ten penultimate leaves were collected at random from each of 51 fields of barley and 29 fields of oat at the late-milk to early-dough stages of development. The leaves were air-dried at room temperature. The percent leaf area diseased (severity) and number of fields affected (prevalence) were calculated for each CD. At the time of rating, the identify of diseases present, based on visual inspection, was also recorded.

RESULTS AND COMMENTS: Leaf spot diseases were found in all barley and oat fields surveyed (Table 1). While moisture conditions were generally favourable to disease development, except in the north-west region of the province, the cool weather experienced in the first half of the growing season appeared to slow disease development so that disease levels were similar to or slightly lower than those in 1999. The average leaf spot severity on flag leaves was trace (<5%) in 12%, slight to moderate (5-25%) in 58%, moderate (26-50%) in 17% and severe (>50%) in 13% of fields surveyed. Disease levels tended to be fairly similar across all crop districts. Leaf spot disease severity in oat was low with the highest levels occurring in the east-central region (CDs 5A, 5B). Most fields had trace or slight levels of disease.

The most common leaf disease in barley was net blotch, caused by *Pyrenophora teres*. Spot blotch (caused by *Cochliobolus sativus*) was the next most common disease and scald (caused by *Rhynchosporium secalis*) was detected on leaf samples from 4 fields in north-western Saskatchewan (CDs 9A, 9B). Plating of leaf samples will be done to confirm these observations and to identify the cause of the oat leaf spots. Crown rust was not found in any oat field.

We gratefully acknowledge the participation of Saskatchewan Agriculture and Food extension agrologists in this survey and financial support from the Saskatchewan Agriculture Development Fund.

Table 1. Distribution and severity of leaf spotting diseases of barley and oat in Saskatchewan fields surveyed at late milk to early-dough stages in 2000.

TITLE / TITRE: STEM RUSTS OF CEREALS IN WESTERN CANADA IN 2000

INTRODUCTION AND METHODS: Surveys of fields and trap nurseries of barley, oat and wheat for incidence and severity of stem rust *(Puccinia graminis* Pers. f. sp. *tritici* Eriks. & E. Henn. and *P. graminis* Pers. f. sp. *avenae* Eriks. & E. Henn.) were conducted in July, August, and September 2000. Infected stem tissue samples obtained from fields and trap nurseries were evaluated for pathotypic specialization on appropriate sets of host differential lines.

RESULTS AND COMMENTS: Environmental conditions were unfavorable for stem rust infection, with low temperatures and frequent rainfall. Stem rust severity on susceptible lines in trap nurseries was at very low levels (<5%) in 2000. All spring wheat cultivars recommended for Manitoba and Saskatchewan have excellent resistance to stem rust, and no stem rust infection was observed in any commercial fields. Barley and oat cultivars recommended for Manitoba and Saskatchewan are susceptible to stem rust infection (Pathotypes QCCJ and NA67, respectively). Little or no stem rust infection was observed in early-planted barley and oat fields. This may be due to escape from infection, unfavorable environmental conditions, or to application of foliar fungicides. In 2000, a significant percentage of cereal fields in eastern Manitoba were sprayed with fungicides for control of foliar and head diseases, which additionally controlled stem rust. Low to moderate levels of infection developed during late summer-early fall on late-planted oat fields, wild barley *(Hordeum jubatum* L.), and wild oat *(Avena fatua* L.).

No new pathotypes of *P. graminis* f. sp. *tritici* were found to threaten Canadian wheat or barley production. The most serious stem rust threat is the continued increase in frequency of pathotypes NA67 and NA76 of *P. graminis* f. sp. *avenae*. These pathotypes are virulent on the effective stem rust resistance genes *(Pg2, Pg9,* and *Pg13)* deployed in Canadian oat cultivars. Since the advent of pathotype NA67 in 1998, the frequency of this pathotype in the oat stem rust population in the eastern prairie region on Canada has risen from about 20% to near 40% in 2000. These two races now threaten oat production in the rust area of the prairies. Identification and incorporation of genes conferring resistance to NA67 and NA76 are underway in the Agriculture and Agri-Food Canada, Cereal Research Centre breeding programs.

TITLE / TITRE: CEREAL VIRUS DISEASE SITUATION IN MANITOBA IN 2000

INTRODUCTION AND METHODS: Virus diseases on cereals in Manitoba monitored in 2000 were barley yellow dwarf (BYD), wheat streak mosaic (WSM) and flame chlorosis (FC). Collaborators identified and collected samples from early June to late August in cereal crops in Manitoba and parts of eastern Saskatchewan. The proportion of plants with (suspected) virus symptoms in surveyed fields was estimated and specimens with and without symptoms collected for testing. Infection with BYDV and WSMV was confirmed by transmission to indicator hosts, and for BYDV, also characterized as to serotype by enzyme-linked immunosorbent assay (ELISA). In addition to confirming identity of causal agents, transmission to indicator host plants was used to assess virulence against historical benchmarks. For WSMV, transmission was by mechanical inoculation to a range of susceptible spring bread and durum wheat hosts; for BYDV, transmission was by cereal aphids to sets of seedlings of a susceptible oat host.

RESULTS AND COMMENTS:

Barley Yellow Dwarf (BYD) - Unlike 1999 (1), losses due to BYD were generally very mild. Cereal aphid populations carrying BYDV were not in evidence in Manitoba until late June, which is similar to most years. Compared to 1999, the proportion of early-arriving cereal aphids that were oat bird-cherry (*Rhopalosiphum padi*), the most efficient vector of the predominant BYDV strain, PAV, was lower and roughly similar to that seen in most years. Although losses were generally mild, there were areas of noticeable losses in later-seeded barley in western Manitoba (near Brandon) and in barley and oat in some areas near Saskatoon. Losses due to BYD in wheat were very small. Consistent with the trend of the last 15-20 years, almost all virus isolates obtained from small grains were of the PAV strain (non-specifically transmitted by the oat bird-cherry aphid).

Wheat Streak Mosaic (WSM) - Localized outbreaks of WSM in spring wheat crops in Manitoba and eastern Saskatchewan in 2000 occurred in the vicinity of infected winter wheat. In affected fields losses were estimated to be between 5 and 10%, generally lower than in 1999 or recent years (1). This may reflect the relatively cool conditions that generally prevailed in June when most spring wheat crops would have been in the critical early growth stages. Unlike 1999, wheat streak mosaic virus (WSMV) was not found at all in oat plants.

Flame Chlorosis (FC) - After a hiatus in 1999, FC was again observed in Manitoba in 2000, albeit only at extremely low levels and only at edges of wheat fields at two sites in the Red River valley south of Winnipeg. However, no FC was found on barley in western Manitoba, where historically it has been most frequently observed and caused the greatest losses (2).

TITLE / TITRE: CEREAL SMUT SURVEYS, 2000

INTRODUCTION AND METHODS: In July 2000, cereal crops were surveyed for *Ustilago hordei, U. nigra, U. nuda, U. tritici, U. avenae* and *U. kolleri* in Manitoba and Saskatchewan. The area was covered by routes from Winnipeg - Estevan - Moose Jaw - Saskatoon - Prince Albert - Melfort - Yorkton - Russell - Minnedosa - Winnipeg, as well as one day trips around Winnipeg, MB. Fields were selected at random at approximately 10 - 15 km intervals, depending on the frequency of the crops in the area. An estimate of the percentage of infected plants (i.e., plants with sori) was made while walking an ovoid path of approximately 100 m in each field. Levels of smut greater than trace (<0.1%) were estimated by counting plants in a one m^2 area at a minimum two sites on the path.

RESULTS AND COMMENTS: Loose smut (*U. tritici*) was found in 26% of the 143 fields of bread wheats surveyed. In most affected fields, levels of infection were trace; two fields had levels of 0.1%. In durum wheat, loose smut was found in 46% of the 26 fields surveyed. In all infested fields, the level of infection was 0.1%. In awned wheats (likely of the CPS wheat class), loose smut was found in 18% of the 11 fields surveyed. In all these infested fields, the level of infection was 0.1%.

As has been the case for several years, very few oat fields had smut (2 of 18 fields surveyed). Infection levels in all positive fields surveyed were trace. Smutted oat plants were infected with *U. avenae*.

A high incidence of smut (*U. nuda*) was found in barley with 61% of the 87 fields surveyed containing infected plants. Incidence was particularly high in 6-rowed barley (71% of 63 fields) with most fields having levels of trace to 0.1 % smutted plants; however, infection levels of 0.5 to 1% smutted plants per field were observed. In 2-rowed barley, 33% of 24 fields were affected with six fields having trace levels and the other two levels of 0.1 %. False loose smut (*U. nigra*) and covered smut (*U. hordei*) were not found.

TITLE / TITRE: CEREAL DISEASE SURVEY IN CENTRAL ALBERTA - 2000

METHODS: Cereal crops were randomly selected approximately every 10 km in Alberta Census District (CD) 8 (north central Alberta) on August 2 and 3. This area encompasses Sylvan Lake on the west, Bashaw on the east and is bordered north and south by Ponoka and Innisfail, respectively. Fields were traversed in an inverted V, with analysis of 5 plants taking place at 3 locations. Leaf diseases were scored on a 0-9 scale, with a 4 rating equal to 1% leaf area diseased (PLAD) on the upper leaf canopy, 5-10 PLAD on the middle canopy and 10-25 PLAD on the lower canopy. Common root rot (CRR) was assessed on a 0-4 scale where 1=trace and 4=severe. Other diseases were rated as a percent of the field affected.

RESULTS AND COMMENTS: The results are presented in Table 1. Central Alberta experienced a wetter than normal June and July which delayed crops somewhat and resulted in generally higher disease levels than seen in 1999. Thirty-three barley fields were examined, 22 of which were 2-row and 11 of which were 6-row barley. For the second year in a row, there was an unusually high number of 2-row barley fields encountered. Disease incidence was generally higher in 2-row than 6-row barley. Scald (*Rhynchosporium secalis*) and spot blotch (*Cochliobolus sativus*) severities were higher in 2-row barley fields while net blotch (*Pyrenophora teres*) severity was higher in 6-row fields. The severities of CRR (*C. sativus* and *Fusarium* spp.) were higher in 2000 than in 1999, but disease incidence was similar. Loose smut (*Ustilago nuda*) occurred at trace levels in about 1/3 of the 2-row and 6-row barley fields surveyed. Bacterial blight (*Xanthomonas campestris*) severity and incidence were higher in 2000 than in 1999. Barley leaf stripe (*Pyrenophora graminea*) was not noted in this survey.

Septoria/Stagonospora leaf blotch (*Septoria tritici*, *Stagonospora nodorum*) was present in all 13 wheat fields examined, at relatively high levels. Tan spot (*P. tritici-repentis*) was not noted in 2000. Glume blotch (*S. nodorum*) was present at low levels in four fields. Take-all (*Gaeumannomyces graminis*) was encountered in six fields at mainly low levels, except for one field with about 60% affected plants. Common root rot was found at levels similar to those of 1999. Powdery mildew (*Erysiphe graminis*) was noted in only one field. In a smaller survey conducted later in the season, stripe rust (*Puccinia striiformis*) was found at low levels in two of the four wheat fields examined.

Table 1. Disease severity and incidence in central Alberta cereal fields in 2000.

TITLE / TITRE: SURVEY OF CORN PESTS IN ONTARIO AND QUEBEC IN 2000

INTRODUCTION AND METHODS: In July, September, and October 2000, the Eastern Cereal and Oilseed Research Centre (ECORC) conducted a corn pest survey in Ontario and Quebec. As in previous surveys, the main purpose was to determine the distribution of the bacterial disease Stewart's wilt (*Pantoea stewartii* = *Erwinia stewartii*) and of viral diseases, such as Maize Dwarf Mosiac (MDM), Sugarcane Mosaic (SCM), Johnson Gross Mosaic (JgM), Maize Chlorotic Dwarf (MCD), Maize Chlorotic Mottle (MCM), Maize White Line Mosaic (MWLM), Wheat Streak Mosaic (WSM), and Barley Yellow Dwarf (BYD). Also recorded were the distribution and severity of other diseases and insects including eyespot (*Aureobasidium zeae*), northern leaf blight (*Exserohilum turcicum*), common rust (*Puccinia sorghi*), common smut (*Ustilago maydis*), head smut (*Sporisorium holci-sorghi* = *Sphacelotheca reiliana*), stalk rot (*Fusarium spp*., and *Colletotrichum graminicola*), ear rot (*Fusarium spp*.), European corn borer (*Ostrinia nubilalis*) and corn rootworm (*Diabrotica longicornis* and/or *D. virgifera*). As well, scouting for any new diseases in Canada was conducted, especially for grey leaf spot (*Cercospora zeae-maydis*).

At each of 114 locations visited between July 13 and October 5, the incidence of each pest and the severity of the predominant pest was recorded. At the same time, Stewart's wilt samples and leaves with virus-like symptoms were collected. ELISA tests for Stewart's wilt and viruses were done in the laboratory by using reagent sets, protocols and antibodies provided by AGDIA Inc. (Elkhart, Indiana 46514, USA).

RESULTS AND COMMENTS:

Fungal leaf diseases: Common rust was found at every location (Table 1) and the severity was generally moderate to high according to the resistance level of hybrids and planting date; only a few commercial hybrids exhibited high resistance. Common rust was found as early as June 17at Ottawa. This is one month earlier than usual. Late planted (late June or July) sweet corn and grain corn only had a few rust pustules in both Ontario and Quebec. This difference in severity resulting from planting date, suggests the original infectious uredospores arrived via southerly winds and rainfall due to much more rain in May and June in 2000 than usual.

Northern leaf blight was found at only 9 locations, and only one farm at Forfar in Leeds and Grenville County, ON had indications of potential severe yield loss. The same hybrid had been planted in this 55 acre field for three years and yielded quite well in both 1998 and 1999, but in 2000 the corn plants died before September 4 due to severe infection of northern leaf blight; yield losses were estimated at near 50%. No blight was found at a farm in St-Philippe, Argenteuil County, QC which had severe northern leaf blight in 1998 but less blight in 1999. The producer eliminated the 1998 crop debris by burning and has used a resistant hybrid since 1999.

Eyespot was found at 39 locations but only one hybrid at Elora, Willington County, ON was found to be highly susceptible. In some areas, a form of cross protection between common rust and eyespot appeared to exist, i. e., the more common rust, the less eyespot and vice-versa. One unknown leaf

disease was found sporadically at two locations in both Ontario and Quebec. Grey leaf spot was not found at any of the locations surveyed in 2000.

Fungal Ear and Stalk diseases: Stalk and ear rots were observed at all locations where the corn matured. *Fusarium* stalk rot, *Pythium* stalk rot (known as 'early death'), and anthracnose stalk rot were observed. Anthracnose stalk rot was a major problem late in the season in the Chatham-Kent areas. Top-die back, a disease caused by the same pathogen as anthracnose stalk rot was widespread during the period September 12-14. As a result, two weeks later, corn plants dried prematurely due to the spread of anthracnose stalk rot. In north Chatham, 20-100% plant breakage above the ear was evident in early October in every field visited. Resistance to this breakage varied among hybrids from all companies. Because increased lodging was expected, many farmers harvested early.

Common smut was found at 69 locations, but severe damage was not observed on commercial hybrids. Head smut was found at only four locations. In a field at the AAFC Greenbelt Farm, Ottawa-Carleton County, ON the head smut-infected area has increased from 75 x 30 m^2 in 1998 and 300 x 100 m^2 in 1999, to 1850 x 400 m^2 in 2000, but the incidence has decreased from 37% to 19% to 6%, respectively. The area expansion is most likely due to spread during combining, but the reason for decreased incidence is unknown. Cladosporium ear rot (*Cladosporium herbarum*) was identified in one farm sample submitted to ECORC.

Insects: Damage from the European corn borer (ECB) was greater in southern Ontario than eastern Ontario or Quebec. In Chatham-Kent, Elgin, Essex, and Middlesex counties, some fields had incidences as high as 50-80% with 20-50% stalk breakage. The ECB damage increased lodging caused by anthracnose stalk rot. Bt corn showed excellent resistance to ECB, resulting in no increase in lodging from anthracnose stalk rot; there was however no effect on the fungal infection rate.

Lygus lineolaris, which usually sucks the leaves resulting in small white spots , caused severe damage on some AAFC breeding lines at Cobden, Renfrew County, ON. The nymph and adult insect sucked on the young tissues in the whorl and left a wide range of transparent tissues. The leaves dried and sometimes tightened around new whorl leaves impeding further plant growth.

Corn rootworm (CRW) damage was observed at 38 locations, but mostly consisted of leaf damage and silk pruning. Root lodging caused by CRW was found only at Winchester in Stormont Dundas and Glengarry County, ON. Aphids were numerous in some late sweet corn and breeding material in the London and Ottawa areas.

Bacterial diseases: Holcus leaf spot (*Pseudomonas syringae*) symptoms were seen only at one location, and no Goss' bacterial wilt (*Clavibacter michiganensis subsp. nebraskensis* = *Corynebacterium nebraskense*) was observed. A total of 73 leaf samples with wilt-like symptoms and 11 kernel samples from Stewart's wilt-affected plants were collected from 42 locations in 12 Ontario and 2 Quebec counties. As shown in Table 1, Stewart's wilt was identified with the ELISA test at 40 locations in Chatham-Kent, Elgin, Essex, Frontenac, Huron, Lambton, Leeds and Grenville, Middlesex, Oxford, Peel, Perth, and Waterloo counties, ON, and Les Maskoutains county, PQ.

All 50 of the samples collected with 'typical' Stewart's wilt symptoms consisting of long streaked lesions with wavy margins tested positive for Stewart's wilt. Seven (30.4%) of the other 23 leaf samples were also positive. Of the 11 kernel samples, 5 (45.5%) tested positive for Stewart's wilt. Severe Stewart's wilt damage was found on late planted sweet corn (planted at the end of June) in the area around London, ON. At Northcrest and Ballymate in Middlesex County , ON, 100% of plants were diseased, about 5-25% plants died, and 10-18% plants were barren. Symptoms differed between sweet corn and grain corn. On sweet corn, the symptoms of Stewart's wilt first appeared as long, narrow, white stripes, then changed to brown; plants were dwarfed and some even died.

Viral diseases: Viral symptoms, such as dwarfing, mosaic, and yellowish streaks were observed in late-planted (planted during the last week of June) sweet corn at 5 locations in Middlesex County, ON and late-planted (planted first week of August) grain corn at north Ridgetown, Chatham-Kent County, ON. Other virus-like symptoms, such as deformation and yellowing were observed at 41 locations. Maize Dwarf Mosaic Virus (MDMV, formerly MDMV-A), Sugarcane Mosaic Virus (SCMV, formerly MDMV-B), and Wheat Streak Mosaic Virus (WSMV) were identified in Ontario; no virus was identified in Quebec by ELISA tests. MDMV was identified at 7 locations in Chatham-Kent and Middlesex Counties, SCMV at 7 locations in Chatham-Kent, Middlesex, and Ottawa-Carleton counties, but WSMV only at Ballymate, Middlesex county.

More virus diseases were detected in later-planted plants. In fields with plants subsequently testing positive for virus, 0, 4-12%, and 70% plants with typical viral symptoms were observed in fields planted in late May (Ottawa-Carleton County), in late June (Middlesex County), and in early August (Chatham-Kent County), respectively. For significant MDM and SCM development, high (viruliferous) aphid populations had to coincide with susceptible growth stages. In normal (early) planted corn, sufficient aphid numbers did not occur until the 10-12 leaf stage allowing plants to escape virus infection. In late-planted corn, higher aphid populations coincided with the susceptible stage (prior to the 8-leaf stage) resulting in infection and visible viral symptoms.

Overall in 2000, common rust and anthracnose stalk rot were more severe than average, likely as a result of the generally cool and wet conditions. European corn borer caused more damage in southern Ontario. Stewart's wilt was less common than in 1999. MDMV, SCMV, and WSMV were primarily found on later planted corn.

TITLE: CROWN RUST OF OAT IN WESTERN CANADA IN 2000

INTRODUCTION AND METHODS: Surveys for oat crown rust (caused by *Puccinia coronata* Cda f. sp. *avenae* Eriks.) incidence and severity were conducted in southern Manitoba from early July to late August, and in eastern Saskatchewan in mid-August. Crown rust collections were obtained from wild oat (*Avena fatua* L.) and commercially grown oat in farm fields, and from susceptible and resistant oat lines and cultivars grown in uniform rust nurseries. The nurseries were located at Brandon, Emerson, and Morden, MB, and at Indian Head, SK. Virulence phenotypes of single-pustule isolates established from the rust collections were identified, using 16 single-gene backcross lines (*Pc38, Pc39, Pc40, Pc45, Pc46, Pc48, Pc50, Pc51, Pc52, Pc54, Pc56, Pc58, Pc59, Pc62, Pc64, Pc68*) as the primary differential hosts. Single-gene lines with *Pc94* and *Pc96* were included in the differential sets as supplemental differentials.

RESULTS AND COMMENTS: Oat crown rust was less severe in southern Manitoba and more severe and widespread in south-eastern Saskatchewan in 2000 than in previous years. Traces of crown rust infection were first observed on wild oat (*Avena fatua* L.) near Emerson, MB, on July 9. Subsequent conditions were cool with above average rainfall. This limited the development of the rust during most of the growing season. By mid-August, crown rust severities ranging from trace to moderate levels (up to 70%) were found on wild oat, and trace to 20% crown rust severities were observed in late seeded commercial oat fields in southern Manitoba. Early seeded fields of susceptible cultivars (e.g., Robert and Riel) escaped damage. Crown rust infections remained at trace levels in field plots of the cultivar AC Assiniboia, and ranged from light to 20% in field plots of Triple Crown. At various locations across eastern Saskatchewan from Estevan to Assiniboia, crown rust severities ranging from 20% to 80% were commonly found on wild oat, and severities ranging from 5% to 40% were found in late seeded commercial oat fields. This was the most severe and widespread occurrence of crown rust in south-eastern Saskatchewan for many years.

To date, 210 single-pustule isolates of *P. coronata* f. sp. *avenae* established from the collections obtained in Manitoba and Saskatchewan in 2000 have been evaluated for their virulence phenotypes using the 18 differential hosts. As in recent years, the prairie rust population in 2000 was predominated by isolates with virulence to genes *Pc38* and *Pc39*; cultivars such as Dumont, Robert, Riel, Belmont, AC Marie and AC Preakness, would have been susceptible to these isolates. Six isolates had virulence to AC Assiniboia and AC Medallion. Thirty-three isolates had virulence to the single-gene line with *Pc48*, a gene found in Triple Crown. One isolate was found to have virulence to lines with the four resistance genes, *Pc38, Pc39, Pc48*, and *Pc68*, combined. This isolate also was virulent to *Pc96.* None of the 210 isolates were virulent to *Pc94*. Genes *Pc48, Pc68, Pc94* and *Pc96* are being used in the oat breeding program at the Cereal Research Centre to develop new cultivars possessing various combinations of these genes for protection against the prairie rust population.

TITLE /TITRE: ERGOT IN COMMON AND DURUM WHEAT IN SASKATCHEWAN IN 2000

INTRODUCTION AND METHODS: Wheat entries in regional variety trials (Saskatchewan Advisory Council on Grain Crops tests) at 22 locations in Saskatchewan were examined for the presence of ergot (*Claviceps purpurea*) in harvested grain. The 22 locations were distributed among four crop production areas (CPA) of Saskatchewan (Saskatchewan Agriculture and Food, 2001). The entries, 18 Canada Western Red Spring (CWRS), 9 Canada Prairie Spring (CPS), 6 Canada Western Extra Strong (CWES) and 5 Canada Western Amber Durum (CWAD), consisted of registered cultivars and advanced co-op lines. Trials were planted at the following locations: 5 in CPA 1 (Assiniboia, Beverley, Fox Valley, Stewart Valley and Swift Current), 9 in CPA 2 (Carlyle, Elrose, Girvin, Saskatoon, Luseland, Outlook, Regina, Scott and Weyburn), 8 in CPA 3 (Battleford, Indian Head, Jedburgh, Kelvington, Lashburn, Melfort, Rosthern and Wynyard) and 3 in CPA 4 (Loon Lake, Nipawin and Shellbrook). For each entry and location, a composite sample of about 300 g from all replicates was analyzed for the presence of ergot bodies. Percent ergot was calculated as (weight of ergot bodies/total weight of samples) X100.

RESULTS AND COMMENTS: Locations where ergot was detected in common and durum wheat are listed in Table 1. The percentage of locations where ergot was present at more than trace levels was 40% for CPA 1, 78% for CPA 2, 75% for CPA 3 and 100% for CPA 4. Girvin, Weyburn and Shellbrook had the highest percent ergot. Overall, ergot levels across the province were somewhat lower than in 1999 (Fernandez et al., 2000). Locations where one or more entries would have been downgraded because of high ergot levels (Canadian Grain Commission, 1991) were Swift Current in CPA 1, Girvin, Outlook and Weyburn in CPA 2, Jedburgh, Kelvington, Lashburn and Melfort in CPA 3, and all locations in CPA 4. In 1999, all locations with ergot had high enough disease levels to cause downgrading in at least one entry. Only seven of these locations were common to 1999 and 2000. Average percent ergot was higher in the CWAD and CWES than in the CWRS or CPS classes.

Average percent ergot of the entries varied from 0.01 to 0.08% (Table 2). As in 1999, the variability among locations precluded any conclusion regarding differences in susceptibility to ergot among entries, although none appeared to be more susceptible than the rest.

TITLE/ TITRE: FUSARIUM HEAD BLIGHT IN COMMON AND DURUM WHEAT IN SASKATCHEWAN IN 2000

INTRODUCTION AND METHODS: The incidence and severity of fusarium head blight (FHB) were assessed in 152 common wheat (Canada Western Red Spring and Canada Prairie Spring) and 61 durum wheat (Canada Western Amber Durum) fields from 20 crop districts (CDs) in Saskatchewan. Heads from 50 plants, between milk and dough stages, were collected randomly from each field and sent to the Crop Protection Laboratory in Regina for disease assessment, pathogen isolation and identification. An FHB index (percent number of heads affected x mean severity of infection/100) was determined for each field. An average FHB index for affected fields in each CD, and for CDs grouped by soil zone (Zone I=Brown, Zone II=Dark Brown and Zone III=Black/Grey soils) was calculated. Kernels from heads with symptoms were surface sterilized in 10% Javex solution for 1 minute and plated on potato dextrose agar for identification of *Fusarium* spp.

RESULTS AND COMMENTS: FHB was found in a total of 60% of the common and durum wheat fields surveyed in Saskatchewan, slightly more than in the two previous years (54-55%) (Table 1; Fernandez et al., 1999;2000). Mean FHB indexes were also higher in 2000 (1.7% in common, 1.2% in durum wheat) than in 1999 (1.1% in common, 0.5% in durum wheat) but lower than in 1998 (3.0% in common, 2.3% in durum wheat). The percentage of infected fields and FHB index were the lowest in Zone I. The highest mean FHB index was found in CDs 1A (south-east), 5A (east-central) and 8B (north-east). Individual durum wheat fields with the highest FHB index (2.2 to 5.8%) were in CDs 1A, 5A and 6A (central). Individual common wheat fields with the highest FHB index (2.0 to 12%) were in CDs 1A, 1B (south-east), 2A, 2B (south-east), 5A, 5B (east-central), 6B (central), 8B (north-east) and 9A and 9B (north-west).

The most commonly isolated *Fusarium* sp. was *F. sporotrichioides*, followed by *F. poae* and *F. avenaceum* (Table 2). The latter two species were more frequent in Zone III than in the other two zones. *Fusarium culmorum* and *F. graminearum* were present in only a few fields. Most of the fields where *F. graminearum* was found were in CD 1A. *Fusarium sporotrichioides* was more prevalent in 2000 (75% of fields) than in 1999 (33%). *Fusarium equiseti*, a common soil saprophyte, but rarely isolated from kernels in the past, was isolated at a frequency of 23% in 2000.

We gratefully acknowledge the participation of Saskatchewan Agriculture and Food extension agrologists in the survey, and financial support by the Agriculture Development Fund.

TITLE / TITRE: LEAF DISEASES OF DURUM WHEAT IN SASKATCHEWAN IN 2000

INTRODUCTION AND METHODS: A survey for leaf diseases of durum wheat was conducted between the milk and dough growth stages in 16 crop districts (CD) in Saskatchewan. In each of 56 fields, 10 flag and 10 penultimate leaves were collected at random and air dried at room temperature. Percent leaf area affected by leaf spots was recorded for each leaf. An average percent infection level (severity) was calculated for each field and CD. Surface disinfested leaf pieces were plated on water agar for identification and quantification of leaf spotting pathogens.

RESULTS AND COMMENTS: Leaf spots were observed on the flag or penultimate leaves of all durum wheat fields surveyed. In most cases, the penultimate leaves were senescent and percent infection could not be assessed. Leaf spot severities in individual fields ranged from 1% to 59% of the flag leaf infected. The highest leaf spot severities (over 20%) were in CDs 1A, 2A, 2B (south-east), 3AS (south-central) and 3BN (south-west) (Table 1).

The most prevalent leaf spotting pathogen was *Pyrenophora tritici-repentis* (tan spot), both in the number of fields where it was present (near 100%) and in the percent leaf area colonized (Table 1). This was followed by *Cochliobolus sativus* (spot blotch) which was most commonly isolated in the southeast (CD 1A). *Septoria tritici* and *S. avenae* f. sp. *triticea* (septoria leaf blotch complex) were more common and widely distributed compared to the past two years (Fernandez et al., 1999; 2000). *Stagonospora nodorum* was isolated at lower levels than in 1999. *Pyrenophora teres* was isolated from leaves of durum wheat in a few fields throughout the province (data not presented).

We gratefully acknowledge the participation of Saskatchewan Agriculture and Food extension agrologists in this survey, and financial support from the Agriculture Development Fund.

TITLE / TITRE: STRIPE RUST OF WHEAT IN MANITOBA AND SASKATCHEWAN IN 2000

INTRODUCTION AND METHODS: During annual surveys of wheat fields for incidence and severity of stem rust *(Puccinia graminis* Pers. f. sp. *tritici* Eriks. & E. Henn.) and leaf rust (*Puccinia triticina* Eriks.) conducted in July, August, and September 2000, stripe rust (*P.striiformis* Westend. f. sp. *tritici*), which is very uncommon in Manitoba and Saskatchewan, was found in many wheat fields over a wide geographic area from eastern Manitoba to eastern Saskatchewan. Leaves infected with stripe rust were collected to determine pathotypic specialization on appropriate sets of host differential lines.

RESULTS AND COMMENTS: Cool conditions and high humidity in Manitoba during June and July were favorable for stripe rust infection. Stripe rust severity in affected wheat fields was mostly at trace levels. However, in one field of McKenzie wheat, severity was estimated at 5%. Genetic resistance to stripe rust infection is variable among wheat cultivars recommended for Manitoba and Saskatchewan. In 2000 a significant percentage of cereal fields in eastern Manitoba were sprayed with fungicide for the control of foliar and head diseases, and these fungicides also will control the rust pathogens. Late-planted fields had little or no infection due to higher daily temperatures that inhibit stripe rust infection.

Stripe rust is a disease that is favored by low (10°C) temperatures and is usually found in the Pacific Northwestern region of North America on spring-sown crops. Yield losses exceeding 70% in susceptible wheat cultivars due to stripe rust infection have been reported in the Pacific Northwest (Line and Qayoum, 1991). Stripe rust overwinters in northwestern and southern USA. In the winter of 1999-2000, unusually high amounts of stripe rust were found in the southern and southeastern USA and the rust progressed northward during the spring and summer (Hughes, 2000). Due to unusually cool environmental conditions and higher than average amounts of inoculum coming into the region, stripe rust was commonly found in wheat fields and experimental plots in the Upper Midwestern region of the USA and in southeastern Manitoba. Higher temperatures in late July and early August reduced or eliminated further spread and infection of stripe rust. In past years, under more normal environmental conditions, stripe rust was not a threat to wheat production in Manitoba and Saskatchewan. If stripe rust becomes a serious perennial problem in this region it will be important to determine the relative susceptibility of the currently registered wheat cultivars and emphasize stripe rust resistance in future cultivars.

TITLE / TITRE: 2000 FUSARIUM HEAD BLIGHT SURVEY OF SPRING WHEAT IN MANITOBA AND EASTERN SASKATCHEWAN

INTRODUCTION AND METHODS: Spring wheat fields were surveyed for fusarium head blight (FHB) in southern Manitoba and south-eastern Saskatchewan between 24 July and 3 August 2000. The incidence and severity of FHB in 126 fields were assessed by sampling 50 to 100 wheat heads at three locations in each field between watery-ripe and medium dough stages of development (average Zadoks growth stage 79.8). Up tp 30 kernels per field from sampled heads were surface-sterilized and incubated on potato dextrose agar under continuous cool white light for 4-5 days to identify the *Fusarium* species present . When more than one *Fusarium* species were present, single spores were grown on carnation leaf agar or synthetic nutrient agar to facilitate identification. The FHB index was calculated as follows: Average incidence X Average severity/100.

RESULTS AND COMMENTS: The disease was present in 96 % of fields. The average FHB index was 7.9%, but the disease was not uniform across the region. The most severely affected areas were the Red River Valley north and south of Winnipeg, and further west as far as Portage between Hwys 1 and 2 where the average index was 10.8%. Many fields had an FHB index of 20-30% and in one field it was as high as 47%. Western Manitoba, including fields near Hwy 3, close to the US border, from Manitou to Melita, and south-eastern Saskatchewan, had low levels of the disease, averaging an FHB Index of 3.5% with a range from 0.1 to 29%. This was in contrast to 1999 when the most severe levels of FHB were found in the Russell area close to the Saskatchewan border. The predominant pathogen was *Fusarium graminearum,* comprising over 96% of the isolations (Table 1). Other species found included *F. sporotrichioides, F. equiseti, F.avenaceum,* and *F. culmorum.* Yield and quality/grade losses were relatively high in central Manitoba in 2000. The majority of fields surveyed were of common wheat. Provincial reports indicate durum wheat fields in south-western Manitoba also were severely affected by FHB. These fields may have been at too early a growth stage to be selected in the survey and, therefore, the subsequent severity of the problem was not recognized.

Table 1. Percent *Fusarium* species isolated from spring wheat in southern Manitoba in 2000.

TITLE / TITRE: SURVEY OF LEAF SPOT DISEASES OF WHEAT IN MANITOBA - 2000

INTRODUCTION AND METHODS: Spring wheat fields were surveyed for leaf spot diseases in southern Manitoba and south-eastern Saskatchewan between July 24 and August 3, 2000. Leaves were collected from 137 spring wheat fields (mostly common wheat) between watery-ripe and soft dough stages of development. Severity of disease on upper and lower leaves was categorized as 0, trace, 1, 2, 3 or 4, with 4 describing dead leaves and 1 lightly affected. Samples of diseased leaf tissue were surface-sterilized and placed in moisture chambers for 5-7 days to promote pathogen sporulation for disease identification.

RESULTS AND COMMENTS: Higher than average rainfall in July and August favoured development of leaf spot diseases, which were moderate to severe in southern Manitoba. Foliar fungicides were widely used in 2000 and disease on the upper leaves was either moderately severe, rating 2.5 to 4, or light, rating trace to 1. Lower leaves were mostly senesced at the time the fields were surveyed. Septoria tritici blotch, caused by *Mycosphaerella graminicola*, occurred in 93 % of fields and accounted for 48.7 % of isolations of pathogenic fungi from foliar lesions (Table 1). Prevalence and severity of tan spot, caused by *Pyrenophora tritici-repentis* was higher than in 1999. The pathogen was found in 74% of fields, and comprised 20.3 % of fungal isolations. Spot blotch, caused by *Cochliobolus sativus* had the third highest prevalence and severity. It was isolated from 71% of fields and accounted for 15.1% of isolations. As in past years *Septoria avenae* was the least commonly isolated leaf spot pathogen, but was found at higher levels than in previous years. Stagonospora nodorum blotch, caused by *Phaeosphaeria nodorum* was found in 25% of fields and comprised 8.3 % of isolations; therefore both prevalence and severity were lower than in 1999. Other pathogenic fungi isolated from the leaf tissue included *Platyspora pentamera,* cause of Platyspora leafspot, *Fusarium equiseti, F. graminearum* and *F. sporotrichioides*. These were all found at low levels and comprised less than 4% of the total isolations.

TITLE / TITRE: LEAF DISEASES OF COMMON WHEAT IN SASKATCHEWAN IN 2000

INTRODUCTION AND METHODS: A survey for leaf diseases of common wheat was conducted in fields randomly selected from each crop district (CD) in Saskatchewan. Ten flag and ten penultimate leaves were collected at random from 134 common wheat (CWRS, CPS and CWES classes) fields at the late-milk to dough stages of development. The percent leaf areas covered by leaf spots and leaf rust were recorded for each leaf, and an average percent severity calculated for each CD. Identification and quantification of leaf spotting pathogens was done by plating surface-sterilized leaf pieces on water agar from leaves selected from most field samples and estimating the relative prevalence of each pathogen identified for each leaf examined. An average percent prevalence was then calculated for each CD.

RESULTS AND COMMENTS: Leaf spot diseases were found in all fields surveyed (Table 1). Although infection levels of flag leaves for individual fields ranged from 'trace' (1-5 % severity) to 'severe' (>50 % severity), severity in most fields was slight to moderate. Average leaf spot severity on the flag leaves tended to be highest in the north-eastern and central regions of the province (CDs 2B, 5B, 6B, 8A, 8B). This pattern was similar to that in 1999, although leaf spot severities were lower in 2000. Leaf rust occurred mainly in the south-eastern and east-central regions of the province (CDs 1A, 1B, 2A, 2B and 5A) and at trace to slight levels, a severity considerably lower than in 1999.

As in 1999, the most prevalent leaf spot disease was tan spot (*Pyrenophora tritici-repentis*), both in the number of fields where it was present and its relative frequency on infected leaves (Table 2). This was followed by the septoria leaf spot complex (*Septoria tritici*, *Stagonospora nodorum* and *S. avenae* f. sp. *triticea*). While *S. nodorum* occurred through the province, it was most common in the central and northern regions of the province. *S. tritici* likewise occurred throughout the province, but was more prevalent than *S. nodorum*. This distribution of the septoria leaf spot pathogens was the reverse of that found in 1999 and likely resulted from cool weather conditions in the summer of 2000, which favoured *S. tritici*. Spot blotch (*Cochliobolus sativus)* also occurred throughout the province, but at relatively low levels.

We gratefully acknowledge the participation of Saskatchewan Agriculture and Food extension agrologists in this survey, and financial support from the Saskatchewan Agriculture Development Fund.

TITLE / TITRE: LEAF RUST OF WHEAT IN WESTERN CANADA IN 2000

INTRODUCTION AND METHODS: Nurseries and commercial fields of wheat in Manitoba and eastern Saskatchewan were surveyed for the incidence and severity of leaf rust (*Puccinia triticina* Eriks.) during July and August 2000. Infected leaf samples were collected for pathotype identification by inoculating spores collected from these leaves onto a set of 16 single gene differential host lines.

RESULTS AND COMMENTS: Wheat leaf rust was widespread but relatively light throughout Manitoba and eastern Saskatchewan during the 2000 crop season. Leaf rust infections were first noticed in Manitoba on June 14 but cool wet weather slowed the spread and development of the disease during late June and early July. In many parts of Manitoba seeding was done earlier than usual, in late April and early May, so much of the wheat crop was reaching maturity in late July and early August. These early seeded fields avoided intense leaf rust pressure because they were mature before the disease developed extensively. Increased use of foliar fungicides in 2000 also decreased the incidence of leaf rust from that in previous years. In surveys done during the last week of July and the first week of August leaf rust was found in most fields, but cultivars such as AC Cora and McKenzie continued to show high levels of resistance. Yield losses were not significant in most fields but late seeded fields of susceptible cultivars may have suffered yield losses in the 5-10% range.

The predominant pathotypes of *P. triticina* isolated from Manitoba and Saskatchewan were MBDS, TGBJ, and THBJ, similar to 1999. Evaluation of isolates from other parts of Canada is in progress.

TITLE/ TITRE: FUNGI ISOLATED FROM CROWNS OF WINTER WHEAT IN SASKATCHEWAN, 1987.

INTRODUCTION AND METHODS: (Note that this report presents data from 1987 not published previously. It is of interest and potential relevance because of the current focus on *Fusarium* fungi, particularly the mix of species occurring in the prairie provinces prior to the contemporary epidemic of fusarium head blight in Manitoba and parts of Saskatchewan - Ed.)

In July, 1987, 40 plants (cv. Norstar) were collected from each of 49 winter wheat fields throughout Saskatchewan. A diamond-shaped sampling pattern was used, with each side being approximately 40 m in length. Leaves and roots were removed from crowns. Crowns were rinsed under running water for 1 hour then surface sterilized (15 sec. 100% ethanol, 45 sec. 10% commercial bleach, and 2 x1 minute sterile distilled water rinses). Subsequently, one tiller was plated on minimal medium to determine the spectrum of fungi present, and a second tiller was plated on Nash Snyder medium (2). After 10 days of incubation at room temperature, putative *Fusarium* colonies were transferred to potato dextrose agar in 9 cm diameter petri plates and grown for 10 days at room temperature. Plugs from non-sporulating cultures were transferred to carnation leaf agar medium (1) and grown under ultraviolet light at 20 C for 2 weeks. The original non-sporulating cultures were 'slashed' to stimulate sporulation (in the case of *Fusarium avenaceum*). Sporulating colonies were identified to species according to spore morphology and colony morphology, pigmentation and rate of growth (fast growing isolates grew to the edge of the plate within 10 days).

RESULTS AND COMMENTS: The most frequent fungi present on crowns plated on minimal medium were *Fusarium spp. Bipolaris sorokiniana* and the opportunistic fungi *Penicillium* spp. and *Alternaria spp.* were also found in low frequencies. *Fusarium acuminatum* was present in crowns at all sites sampled. *Fusarium culmorum, F. poae, F. oxysporum* and *F. equiseti* were isolated from 29, 10, 14 and 92 % of the fields, with equal distribution across the province. *Fusarium avenaceum* was present in 37% of the fields, with the majority of these being in the northern part of the province in the gray-black soil zone.

TITLE / TITRE: FUSARIUM HEAD BLIGHT SURVEY OF WINTER WHEAT IN 2000 IN ONTARIO

INTRODUCTION AND METHODS: Winter wheat fields were randomly selected at harvest on farms across southern Ontario. Mature wheat spikes were harvested using hand shears from 10 areas of approximately $2m^2$ close to the center of each field. The spikes were threshed with an Almaco stationary plot thresher (model VPT-OSC). Deoxynivalenol (DON) was extracted from a 20-g subsample in 100 mL of methanol and water (1:9), and quantified with the commercial preparation EZ-Quant DON Plate Kit (Beacon Analytical Systems, Inc., Scarborough, ME). The limit of detection was 0.2 ppm. Sixty kernels per field were surface-sterilized in 0.16% NaOCl (diluted commercial bleach) for three minutes, air dried and placed on acidifed potato dextrose agar. The agar plates were incubated for seven days under a 12:12 hr light/dark cycle, at room temperature. *Fusarium* colonies were subsequently transferred to carnation-leaf agar, and incubated as above. Species identification was based on Nelson et al. (1983) and Burgess et al. (1988).

RESULTS AND COMMENTS: The highest percentage of *F. graminearum*, and DON content (ppm) were observed in Grey county (averaging 18.9 %, and 3.4 ppm), followed by Lambton, Middlesex, Essex, and Kent counties (Table 1). Fusarium head blight was present in 91 % of the fields examined. *Fusarium graminearum* was the predominant species followed by *F. poae, F. sporotrichioides, F. subglutinans*. Based on these results, fusarium head blight caused significant losses in Ontario in 2000. By contrast, in 1999 only trace levels of *F. graminearum* and DON were detected (data not shown).

TITLE / TITRE: FUSARIUM HEAD BLIGHT OF WINTER WHEAT IN MANITOBA IN 2000

INTRODUCTION AND METHODS: The occurrence of fusarium head blight (FHB) in winter wheat in southern Manitoba was assessed by surveying 47 farm fields from July 13 to 23, 2000. Because winter wheat is not widely grown in Manitoba (in 2000 it was planted on about 2% of the total wheat acreage - Manitoba Crop Insurance Corp.) the fields were not surveyed at random; rather, their locations were specified by Manitoba Agriculture extension personnel and confirmed by contacting producers. Fusarium head blight in each field was assessed by rating a minimum of 80-100 plants at each of 3 locations for percentage of infected spikes (disease incidence), and for the average proportion of the head affected (severity). Disease levels were calculated as the 'FHB Index' (% incidence x % severity / 100). Ten affected heads closest to each of the 3 plant clumps sampled were collected from each location, placed in plastic bags and frozen. Subsequently, 50 seeds from blighted portions of heads were surface-sterilized in 0.3% NaOCl for 3 min., air-dried, and plated onto potato dextrose agar to quantify and identify the *Fusarium* spp. present.

RESULTS AND COMMENTS: Conditions initially were cool and relatively dry, and unfavourable for development of FHB in Manitoba, but by mid-June frequent and above-normal levels of rain ensued, and persisted for the remainder of the growing season. Winter wheat normally flowers earlier than spring-seeded crops, and because of this is considered to escape FHB infection in some years. Despite apparent adequate moisture when winter wheat headed/flowered in 2000, levels of FHB in the crop were relatively low. Possibly, inoculum was not yet abundant due to prior cooler and drier conditions.

Of the 47 fields surveyed, six had no plants with visible symptoms of FHB. Overall, incidence of FHB was 8.2% (range 0 - 40%), severity 13.6% (range 0 - 38%) and the FHB Index 1.6% (range 0 - 15.2%). As such, FHB was estimated to have caused yield losses in commercial winter wheat of about 0.5%. This yield loss is considerably lower than that estimated in 1998, but higher than that in 1999 (Tekauz et al. 2000).

The *Fusarium* spp. and their levels on seed are listed in Table 1. As has been normal for all types of wheat grown in Manitoba, *F. graminearum* was the principal pathogen.

TITLE / TITRE: LEAF SPOTS OF WINTER WHEAT IN MANITOBA IN 2000

INTRODUCTION AND METHODS: Foliar diseases of winter wheat in Manitoba were assessed by surveying 47 farm fields from July 13 to 23, when crops were at the early milk to soft dough stage (ZGS 68-86). Because winter wheat occupies a small acreage in Manitoba (in 2000 it was planted on about 2% of the total wheat acreage - Manitoba Crop Insurance Corp.) the farm fields were not surveyed at random; rather, their locations were specified by Manitoba Agriculture extension personnel and confirmed by contacting producers. Fields surveyed were located in southern Manitoba, in the area bounded by Hwy #16 and the US border, Brandon in the west and Dugald to the east. Disease severity was recorded by sampling approximately 10 plants along a diamond-shaped transect of about 50 m per side, beginning near the field edge. Severity ratings were taken on both the upper (usually the flag leaf) and lower leaf canopies, using a six-category scale: 0 or nil (no visible symptoms); trace (<1% leaf area affected); very slight (1-5%); slight (6-15%); moderate (16-40%); and severe (41-100%). Infected leaves with typical symptoms were collected at each site and dried and stored in paper envelopes. Surface-sterilized pieces of infected leaf tissue were placed in moist chambers for 3-5 days to identify the causal pathogen(s) and determine the disease(s) present.

RESULTS AND COMMENTS: Conditions in Manitoba in 2000 were generally cool and dry in the early part of the growing season (to early June) and then became warmer and quite wet. Thus, winter wheat and early-seeded spring crops suffered relatively little damage from leaf spots, compared to crops seeded later, which evolved for a longer period during conditions more conducive to leaf spot development.

Leaf spots were observed in the upper and/or lower leaf canopies of all winter wheat fields surveyed. Disease severities in the upper canopy were nil, trace or very slight in 21 % of fields, slight in 45%, moderate in 17%, severe in 8% and senescent in 9%. Respective severity categories in the lower canopy were tabulated as 2%, 15%, 21%, 7% and 55%. Based on disease development in the upper canopy (>60% of fields with only trace to moderate leaf spotting), foliar diseases in winter wheat in 2000 caused little damage, likely less than a 2% yield loss. This is less damage than observed in 1999. Spot blotch, caused by *Cochliobolus sativus*, and tan spot, caused by *Pyrenophora tritici-repentis,* were the most prevalent diseases (Table 1), but the contribution of tan spot to the leaf spot complex was considerably lower than found in 1999 (Tekauz et al. 2000).

TITLE: SURVEY OF FUSARIUM WILT AND OTHER CANOLA DISEASES IN ALBERTA, 2000

METHODS: A total of 90 *Brassica* fields, most of which were *B. napus* (except as noted), were surveyed between August 2 and August 24 in the important canola production areas of Alberta, including the north Peace (20 fields), south Peace (30), central (10), east central (19), and south (11). The fields were surveyed before swathing, mostly at crop growth stages 5.1 to 5.3 (Harper and Berkenkamp, 1975). Disease assessments were made by rating 100 randomly selected plants from each field. The presence or absence of lesions on each plant was determined to give percent disease incidence for the following diseases: sclerotinia stem rot (*Sclerotinia sclerotiorum*), blackleg (*Leptosphaeria maculans*), fusarium wilt (*Fusarium spp.*), foot rot (*Fusarium spp., Rhizoctonia solani*), brown girdling root rot (*Rhizoctonia solani*), aster yellows (AY phytoplasma), and staghead (*Albugo candida*). For sclerotinia stem rot, each plant was scored for either a main stem lesion or an upper stem or pod lesion. For alternaria pod spot, (*Alternaria brassicae, A. raphani*), the percent severity of lesions on the pods of each plant was assessed (Conn et al., 1990). If alternaria pod spot was observed in a field, but at a level estimated to be below 1%, the disease was recorded as a “trace”. When other diseases were observed in a field, but not in the sample of 100 plants, the disease was also recorded as a “trace”. When calculating means, all trace values were recorded as 0.1%. The results for each region were combined and mean disease incidence or severity values were determined.

RESULTS AND COMMENTS: Fusarium wilt was observed in 14 of the 90 fields, and incidence values ranged from 0 to 72%. Mean incidence was by far the highest in the east central area while no fusarium wilt was reported in the south or the south Peace (Table 1). Plants with symptoms of both fusarium wilt and blackleg were observed in two fields in the Medicine Hat area; these plants were not included in the calculations of fusarium wilt incidence due to the difficulty in reliably distinguishing symptoms. The provincial average was 2.0%. This disease was first reported in 1999 (Lange et al., 2000), and the incidence observed this season represents a potential spread that should be watched closely.

Sclerotinia stem rot was observed in 68 of the 90 fields and incidence values ranged from 0 to 53% for main stem lesions and from 0 to 67% for upper stem/pod lesions. Mean incidence was highest in the east central region and lowest in the south, where there was no sclerotinia reported (Table 1). The provincial average was 7.3% for main stem lesions and 5.4% for upper stem/pod lesions.

Blackleg was found in 38 of the 90 fields and incidence values ranged from 0 to 66%. Mean incidence was by far the highest in the east central area, while values in all other areas were low (Table 1). The provincial average incidence was 5.6%. In at least two fields, a moderately resistant cultivar was found to have a high or fairly high level of blackleg. In a field near Sedgewick, 66% of cv. LG3345 plants rated had blackleg lesions, while a cv. Quest field near Ryley (Vegreville area) showed a 26% incidence of blackleg.

Foot rot was observed in 17 of the 90 fields, and incidence values ranged from 0 to 47%. Mean incidence was highest in the central region followed by the east central region and lowest in the south Peace, where none was reported (Table 1). The provincial average was 1.6%.

Brown girdling root rot was highest in the Peace, with the north Peace higher (14%) than the south Peace (11%), but negligible (0.2% or less) in the rest of the province (Table 1). It was found in 53 of the 90 fields, and incidence values ranged from 0 to 36%.

Aster yellows was observed in 22 of the 90 fields, with incidence values ranging from 0 to 12%, although all but one field (near Vegreville) showed values of 3% or less. Low values across the province gave a provincial average of only 0.3%; however, general field observations indicated that aster yellows was more prevalent in 2000 than in previous years. An unusually high amount of purpling of canola was noticed in many fields across the province. Preliminary tests indicate that this might be related to aster yellows infection, but further testing is required.

Staghead was found in 15 of the 90 fields, with incidence values ranging from 0 to 20% and a provincial average of 0.6%. Usually the fields either contained *B. rapa*, or the staghead was on volunteer *B. rapa* in *B. napus* fields. Two *B. rapa* fields near Beaverlodge showed significant levels (20% each). The south Peace had the only incidence over 1%, with a 1.6% value.

Alternaria pod spot was found in 57 of the 90 fields. The highest severity (8%) was found in a field near Bonnyville. The provincial average was 0.4%, indicating that alternaria severity levels were below average in 2000.

TITLE: **SURVEY OF CANOLA DISEASES IN SASKATCHEWAN, 2000**

METHODS: A total of 103 fields of *Brassica napus* were surveyed between August 14 and 23 in the major canola production regions of Saskatchewan including the north-east (17), north-central (17), north-west (17), east-central (28), central (8) and south-east (16). Canola fields were surveyed before swathing and when the crop was between growth stages 5.2 and 5.3 (Canola Council of Canada). Disease assessments were made in each field by collecting 20 plants at each of 5 sites separated by at least 20 m and 20 m from the edge of the field. The presence or absence of lesions on each plant was determined to give percent disease incidence for the following diseases: sclerotinia stem rot (*Sclerotinia sclerotiorum*), blackleg (*Leptosphaeria maculans*), aster yellows (AY phytoplasma), and foot rot (*Rhizoctonia, Fusarium*). For sclerotinia stem rot, each plant was scored for either a main stem lesion or an upper branch/pod lesion. For blackleg, each plant was scored for either a severe basal stem canker or any other type of blackleg stem lesion. For alternaria pod spot (*Alternaria brassicae*, *A. raphani*), the percent severity of lesions on the pods of each plant was assessed. If alternaria pod spot was present in a field, but at a level estimated to be below 1%, the disease was recorded as a “trace”. Similarly, when the other diseases were observed in a field, but not in the sample of 100 plants, the disease was recorded as a “trace”. When calculating means, all trace values were counted as 0.1%. Field results were combined for each region and mean disease incidence or severity values were determined.

RESULTS AND COMMENTS: Sclerotinia stem rot was observed in 81 of the 103 fields surveyed and incidence values ranged from 0 to 44% for main stem lesions and from 0 to 52% for upper branch/pod lesions. Mean incidence was highest in the north-central region, followed closely by the north-east region and lowest in the east-central and south-east regions (Table 1). The overall mean incidence values for the province were 8% main stem lesions and 6% upper branch/pod lesions, indicating a yield loss to canola producers of approximately 7% (Morrall et al., 1984). Incidence values were lower in 2000 than 1999 but were similar to most other years (Pearse et al. 2000; Canola Council of Canada; R.A.A. Morrall, unpublished data). Although weather conditions in some parts of the province were conducive to sclerotinia stem rot, canola crops were generally less dense and lower yielding this season as a result of environmental stresses.

Blackleg was observed in 71 of the 103 fields surveyed. Mean incidence values ranged from 0 to 17% for basal stem lesions and 0 to 24% for lesions occurring elsewhere on the stem. Blackleg incidence values were highest in the north-west region, moderate in the north-central region and relatively low elsewhere in the province (Table 1). The overall mean incidence values for the province were 1% for basal stem cankers and 3% for lesions found elsewhere on the stem. Approximately 68% of blackleg lesions were scored as occurring not as basal stem cankers but elsewhere on the stem, indicating limited impact on seed yield and quality.

Aster yellows was observed in 92 of the 103 fields surveyed. Overall mean incidence for the province was 1.6% (Table 1). Incidence ranged from 0 to 10%. Although aster yellows incidence was highest in the north-central region, it was prevalent in all regions of the province surveyed. Aster yellows incidences were slightly higher in 2000 and 1999 than in previous years. This suggests that environmental conditions may have been favourable for the early and abundant migration of leafhoppers into the province.

Foot rot was observed in 40 of the 103 fields surveyed. Disease incidence ranged from 0 to 14% with the highest incidence in the north-east region, followed closely by the north-central and central regions (Table 1). The overall mean incidence for the province was 1.2%.

Alternaria pod spot was observed in 86 of the 103 fields surveyed but mostly at trace severity levels. The highest mean severity was observed in the south-east region (Table 1). In late summer, the south-east region experienced periods of high relative humidity, conditions that favour pod spot development. This survey was conducted before swathing so severity may have been lower than at harvest, when pod spot development typically increases.

Fusarium wilt (*Fusarium avenaceum*) was confirmed in one sample collected in the south-east region (Lange et al., 2000). There were no reports of brown girdling root rot or staghead in any of the fields surveyed.

TITLE: DISTRIBUTION, PREVALENCE AND INCIDENCE OF CANOLA DISEASES IN MANITOBA (2000)

METHODS: In August and September of 2000, 317 canola crops were surveyed in the eastern/interlake (56), southwest (101), northwest (78) and central (82) regions. All crops were *Brassica napus*. All crops were assessed for the prevalence (percent crops infested) and incidence (percent plants infected per crop) of sclerotinia stem rot (*Sclerotinia sclerotiorum*), aster yellows (phytoplasma), staghead (*Albugo candida*), foot rot (*Fusarium* spp. and *Rhizoctonia* sp.), blackleg (*Leptosphaeria maculans*) and fusarium wilt (*Fusarium* spp.). Blackleg lesions that occurred on any part of the canola stem were assessed separately from basal stem cankers. The prevalence and percent severity of alternaria pod spot (*Alternaria* spp.) was determined.

In each canola crop, 100 plants were selected in a regular pattern starting at a corner of the field or at a convenient access point. The edges of the fields were avoided. Twenty plants were removed from each of five points of a "W" pattern in the field. Points of the "W" were at least 20 paces apart. All plants were pulled up, removed from the field and examined for the presence of diseases.

RESULTS: A number of diseases were present in each of the four regions of Manitoba. Sclerotinia stem rot and blackleg were the most prevalent diseases throughout the province (Table 1). The prevalence of sclerotinia-infested crops ranged from a high of 92% in the southwest region to 68% in the eastern/ interlake region with a provincial mean of 81%. This increased from a prevalence of 60% in 1999 (McLaren and Platford, 2000). Mean disease incidence ranged from 15% in the southwest region to 8% in the eastern/interlake region. The provincial mean of 14% was greater than in 1999 and probably resulted in about a 7% yield loss. In 2000, moist conditions during late June and July were favourable for the development of sclerotinia stem rot and produced conditions that increased disease risk in many areas.

Blackleg basal cankers occurred in 45% of the crops surveyed in 2000 with mean disease incidence ranging from 14% in the southwest region to 3% in the northwest region and a provincial mean of 9%. The average incidence was higher in 1999, with the highest value of 29% occurring in the southwest region (McLaren and Platford, 2000). When blackleg was detected in the crops surveyed in 2000, severe symptoms were observed in many cases. These caused a yield loss estimated at about 5% on a province-wide basis.

The mean prevalence of blackleg stem lesions was less than during the last two field seasons, with 72%, 66% and 54% of crops infested with stem lesions in 1998 (McLaren and Platford, 1999), 1999 (McLaren and Platford, 2000) and 2000, respectively. The mean incidence in 2000 was 7%, similar to that in 1999 (McLaren and Platford, 2000).

The severity of alternaria pod spot was low, with means of <3% in the southwest and northwest regions (Table 2). No alternaria was reported on the 100-plant samples from surveyed crops in the central and eastern/interlake regions. The highest prevalence (31%) occurred in the southwest region (Table 1). In

the northwest region, 22% of the crops surveyed for alternaria pod spot were infested. These values decreased from prevalences of 97% in the southwest region and 95% in the northwest region in 1999. Although this disease was most prevalent in the western part of the province in both years, above normal precipitation was received in western and southwestern Manitoba in 1999.

The prevalence of aster yellows in the 2000 surveyed crops ranged from 70% in the southwest region to 5% in the central region with a provincial mean of 40%. This decreased from a prevalence of 56% in 1999 (McLaren and Platford, 2000). The average disease incidence was 2% in the central region and 3% in all other regions.

Other diseases that were observed in the surveyed crops were foot rot (in 4% of fields) and staghead (on volunteer *B. rapa*) in 1% of the fields. The mean disease incidence for foot rot was below 5%. The disease incidence for staghead was always below 5%.

Fusarium wilt was observed for the first time in 1% of canola fields in Manitoba. The disease incidence was below 5%.

TITLE: SEED-BORNE PATHOGENS OF CHICKPEA IN SASKATCHEWAN IN 2000

METHODS: The results of agar plate tests conducted by four Saskatchewan companies on seed samples from the 2000 crop were summarized separately for kabuli and desi chickpea. The tests were conducted mainly to detect the pathogens causing ascochyta blight (*Ascochyta rabiei*), botrytis blight [grey mould] (*Botrytis cinerea*) and sclerotinia stem and pod rot (*Sclerotinia sclerotiorum*). Not all samples were tested for *Botrytis* and *Sclerotinia* but all were tested for *Ascochyta*. Figures for *Ascochyta* and *Botrytis* were classified according to crop districts [CD] of Saskatchewan (1). However, this was not done for *S. sclerotiorum* because infection levels are generally so low that comparisons of means would be valueless.

It was unknown which of the samples came from crops that had been treated with registered fungicides. Bravo (a.i. chlorothalonil) is widely used as a foliar protectant on chickpea. Apron (a.i. metalaxyl) is generally used as a seed treatment on kabuli chickpea.

RESULTS AND COMMENTS: In most areas of Saskatchewan the growing season started with relatively dry conditions that resulted in early completion of seeding in May. From June to early August rainfall amounts varied from about 50% to 200% of normal in different crop districts, with the wettest conditions generally in the northeast, southeast and south central areas. These included some of the main areas of chickpea production in southern Saskatchewan and contributed to extensive spread of ascochyta blight in many crops as well as rank growth that contributed to botrytis blight infection. In late August good harvest weather prevailed throughout the province, but in early September rain and warm humid weather caused deterioration of crop quality in many areas. The average provincial yield (kabuli and desi combined) was similar to that in 1999, but only about 95% of the seeded area was harvested, largely due to crop failures due to diseases.

By mid-December almost 1200 chickpea seed samples (nearly 900 kabuli, 200 desi and about 100 non-specified) had been tested by the four companies. The 40% increase over 1999 (2) reflects a large increase in acreage.

Levels of seed-borne *Ascochyta* varied among crop districts (Table 1), and were generally lowest in CD 2A, 4A and 4B. The provincial mean for desi chickpea was lower than that for kabuli, possibly reflecting a difference in leaf types between the two. The majority of kabuli cultivars grown in Saskatchewan have unifoliolate leaves while the majority of desi cultivars have fern-type leaves. Agronomists and growers noted during the season that ascochyta blight tended to be more severe on chickpea crops with unifoliolate leaves than on those with fern-type leaves (mainly desi cv. Myles and kabuli cv. B-90). The

maximum recorded values of ascochyta seed infection were 46.25% in kabuli for a sample from CD 6A and 15.25% in desi for a sample from CD 3A-S.

The overall percentages of samples in which no ascochyta was detected were 27 for kabuli and 41 for desi. Direct comparisons with previous years of mean infection levels or percent samples with no infection are not possible because in previous years figures were not separated for kabuli and desi chickpea (2,3,4). However, the mean infection levels for both kabuli and desi in 2000 were higher than the overall mean in 2000; in turn, this figure was higher than the corresponding figures for 1998 and 1997. Clearly ascochyta blight was a major problem in chickpea production in 2000, despite widespread use of moderately resistant cultivars and applications of Bravo.

Botrytis was detected in 48% of the kabuli samples tested and 72% of the desi samples (Table 2). In 1999 the corresponding figure for both types of chickpea combined was 50%, weighted 2/3 towards kabuli (2). Thus, there was probably little change in mean prevalence of *Botrytis* on kabuli chickpea between 1999 and 2000. However, mean provincial infection levels in 2000 were 1.7% for kabuli and 2.5% for desi, both substantially higher than the combined mean of 0.7% reported in 1999. The highest individual values recorded in 2000 were 24.25% in kabuli and 23.5% in desi, both for samples from CD 2A.

The difference in *Botrytis* infection levels between kabuli and desi seed can probably be attributed mainly to the tendency of growers to plant desi cultivars in areas where chickpea is less well adapted (more rainfall and heavier soils). These conditions favor rank growth and *Botrytis* infection in late summer. Thus, the provincial average infection level for *Botrytis* in kabuli is highly influenced by the fact that nearly 30% of the samples came from CD 4A and 4B, where chickpea is well adapted and *Botrytis* levels were low (Table 2). On the other hand, only 9% of desi samples came from CD 4A and 4B and this had less effect on the provincial average. However, in contrast to 1999 (2), high *Botrytis* levels did occur within some of the area of optimum adaptation of chickpea in Saskatchewan (i.e. CDs 3A-S, 3B-N, 3B-S, 4A, 4B, and 7A) because of above-normal rainfall.

Sclerotinia sclerotiorum was isolated from a small percentage of kabuli and desi chickpea seed samples in 2000 and in these most commonly at levels of 1.0% or less.

TITLE / TITRE: DISEASE SURVEY OF CHICKPEA IN WEST-CENTRAL SASKATCHEWAN IN 2000

INTRODUCTION AND METHODS: A survey for chickpea diseases was conducted in fields randomly selected near Rosetown, Eatonia, Lemsford, Lancer, Cabri, Pennant, Success, Stewart Valley and Demaine in west-central Saskatchewan (Fig. 1). Five plants in the pod-fill stage were sampled at each of four random sites for each of 59 chickpea fields between July 17 and 21, 2000. Root disease severity was estimated using a scale of 0 to 4 (0 = no disease, 1 = small lesions, 2 = large lesions, 3 = plant girdled, and 4 = plant dead). The incidence of ascochyta blight and other diseases was recorded. All diseased plant samples were cultured onto various agar media in the laboratory to retrieve causal pathogens. Information on cultivar and seed treatment were obtained from the growers, and the rates of seed treatment were provided by Gustafson®. Data were analysed using the general linear model with the SAS System 6.12.

RESULTS AND COMMENTS: Ascochyta blight (*Ascochyta rabiei*) and root rot (*Fusarium* spp., *Pythium* spp., and *Rhizoctonia solani*) of chickpea were most the common diseases observed in the fields and causal pathogens were recovered from plant samples. Alternaria leaf spot (*Alternaria* spp.) and sclerotinia stem rot (*Sclerotinia sclerotiorum*) were also present (Table 1).

Overall, ascochyta blight was identified in 57 of the 59 fields surveyed with a fairly high incidence in each field. There was no significant difference in the incidence of ascochyta blight across the surveyed area. There was no significant difference (P = 0.22) in incidence of *Ascochyta* infection between Desi cvs. CDC Anna and Myles and Kabuli cvs. CDC Yuma, Evans, Sanford, B90, Dwelley and CDC Xena (data not shown). Root rot diseases were observed in 32 of the 59 fields surveyed. In most, *Fusarium* and *Pythium* were identified as the causal agents. A few of the samples had *Rhizoctonia*-induced root disease (Table 1). However, root rot incidence varied with location and seed types. There was a much higher incidence of root rot diseases in the areas of Demaine, Rosetown, Pennant and Success than in the other areas surveyed. Kabuli cultivars usually had a lower root rot incidence than the Desi cultivars (Table 2), probably because seed treatment was not applied in 7 of the 11 Desi chickpea fields.

Only three cultivars of Kabuli exhibited low root rot with disease incidence ranging from 0 to 5.0% and disease severity less than 0.1 on the 0 - 4 scale. Chemical seed treatments were applied in 52 of the 59 fields by commercial seed suppliers. Three different seed treatments were used, including Crown (92 g/L carbathiin + 58 g/L thiabendazole) at 300 mL + Apron (metalaxyl) at 16 mL/100 kg seed, Vitaflo 280 (thiram 130 g a.i./L + carbathiin 150 g a.i./L) at 260 mL + Apron (metalaxyl) at 16 mL/100 kg seed, and Apron (metalaxyl) alone at 16 mL/100 kg seed. All three treatments significantly (P # 0.01) reduced root rot diseases compared to non-treated fields, although there was no difference among the three seed treatments (Table 3).

We gratefully acknowledge the assistance of David Nobbs of Gustafson® at Rosetown, Saskatchewan in carrying out this survey.

Table 1. Summary of common diseases observed on chickpea in west-central Saskatchewan in 2000.

DISEASE	CAUSAL AGENT	NO. FIELDS INFESTED	LOCATION
Ascochyta blight	*Ascochyta rabiei*	57	Cabri, Demaine, Eatonia, Lancer, Pennant, Rosetown, Stewart Valley, Success
Fusarium root rot	*Fusarium* spp.	15	Demaine, Eatonia, Lancer, Pennant, Rosetown
Pythium root rot	*Pythium* spp.	13	Demaine, Eatonia, Lancer, Pennant, Rosetown
Rhizoctonia root rot	*Rhizoctonia solani*	4	Cabri, Eatonia, Success.
Alternaria leaf spot	*Alternaria* spp.	3	Demaine, Eatonia.
Sclerotinia stem rot	*Sclerotinia sclerotiorum*	3	Eatonia, Success.

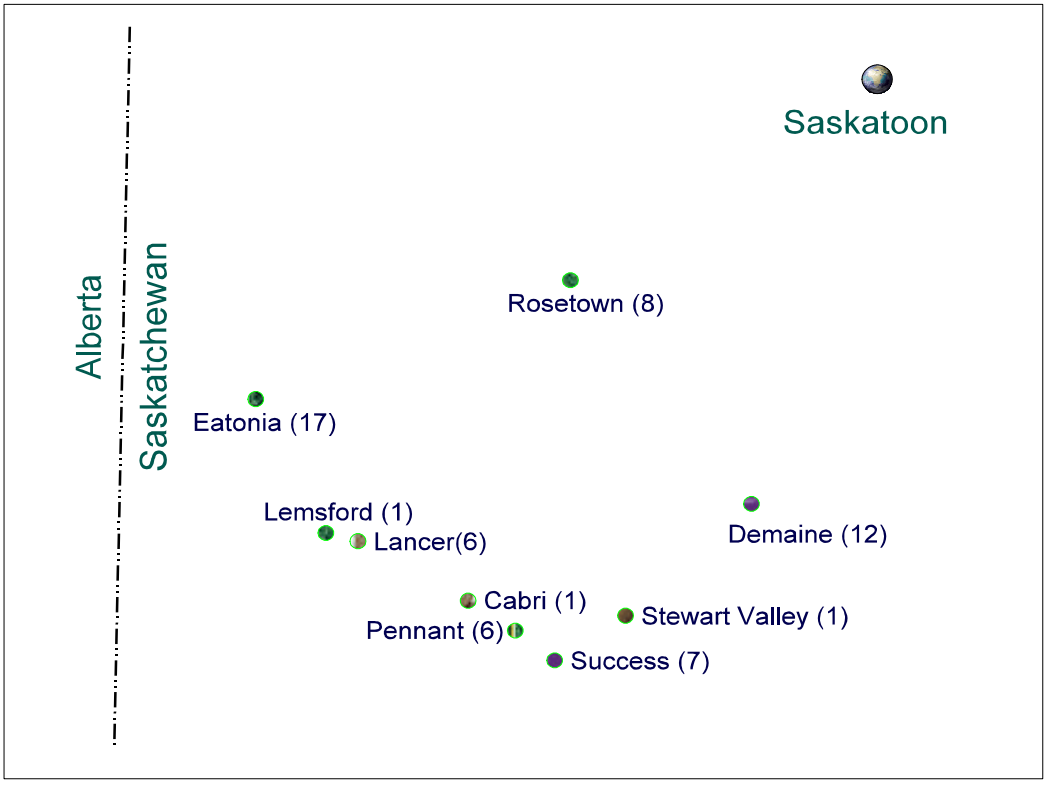
[1] Root rot diseases include fusarium, pythium and rhizoctonia root rots. Means are presented with their ranges in parentheses under each category.

[2] The seed treatments were applied by the commercial seed suppliers as Crown at 300 mL + Apron at 16 mL/100 kg seed, Vitaflo 280 at 260 mL + Apron at 16 mL/100 kg seed, and Apron alone at 16 mL/100 kg seed.

Figure 1. Distribution of surveyed chickpea fields in west-central Saskatchewan in 2000. Numbers in parentheses indicate the number of fields surveyed near each town.



CROP: Field bean

LOCATION: Manitoba

NAME AND AGENCY:
A.G. Xue* and L. Yager
Agriculture and Agri-Food Canada Research Centre, Unit 100-101, Route 100,
Morden, Manitoba R6M 1Y5.
*Current address: Eastern Cereal and Oilseed Research Centre, Agriculture and Agri-Food Canada,
Room 2091, K. W. Neatby Building, 960 Carling Avenue, Ottawa, Ontario, Canada K1A 0C6.

TITLE: DISEASES OF FIELD BEAN IN MANITOBA IN 2000

METHODS: Crops of field bean were surveyed for root diseases at 33 different locations and for foliar diseases at 36 locations in Manitoba. The survey for root diseases was conducted in the first week of July when plants were at the second to third trifoliate stages, and for foliar diseases was conducted in the last week of August when the plants were at the late pod-filling to early maturity stages. The crops surveyed were chosen at random from regions in southeast and south-central Manitoba, where most field bean is grown. Ten plants were sampled at each of three random sites for each crop surveyed. Diseases were identified by symptoms. The severity of root diseases was estimated using a scale of 0 (no disease) to 9 (whole roots/lower stem severely diseased). Five to ten roots with disease symptoms per field were collected for isolation of fungi in the laboratory in order to confirm the visual assessment. Severity of foliar diseases was estimated using a scale of 0 (no disease) to 5 (whole plants severely diseased). White mould was rated as a percentage of plants infected.

RESULTS AND COMMENTS: Root rots were observed in all 33 fields surveyed and a total of four diseases was recorded (Table 1). Of the four diseases, rhizoctonia root rot (*Rhizoctonia solani*) and fusarium root rot (*Fusarium solani* f. sp. *pisi*) were the most prevalent, and were observed in 24 and 21 of the 33 fields surveyed, respectively. The mean severity for rhizoctonia root rot was 1.9 and for fusarium root rot was 1.8 on the 0-9 scale. Severe infection by either disease was not observed. Other root diseases including pythium root rot (*Pythium* spp.) and aphanomyces root rot (*Aphanomyces euteiches*) were minor and each was observed in only three crops.

Four foliar diseases were observed in the 36 fields surveyed (Table 2). Bacterial blights (common bacterial blight *(Xanthomonas campestris* pv.*phaseoli*), halo blight *(Pseudomonas syringae* pv. *phaseolicola)* and bacterial brown spot *(Pseudomonas syringae* pv. *syringae*) were observed in all 36 fields surveyed and were the most severe diseases of field bean in Manitoba in 2000. Yield reduction due to bacterial blights was estimated to be at least 10%. Anthracnose (*Colletotrichum lindemuthianum*) was observed in eight crops, but the intensity was generally low for the infested crops. Other diseases including white mold (*Sclerotinia sclerotiorum*) and rust *(Uromyces appendiculatus)* were observed in two and one crops, respectively. These diseases did not appear to cause significant damage to the field bean crops.

Table 1. Intensity of root diseases in 33 crops of field bean in Manitoba in 2000.

DISEASE	NO. FIELDS AFFECTED	DISEASE INTENSITY IN AFFECTED FIELDS[1]	
		Mean	Range
Rhizoctonia root rot	24	1.9	0.8-3.6
Fusarium root rot	21	1.8	0.8-3.6
Pythium root rot	3	3.7	1.4-7.9
Aphanomyces root rot	3	4.4	1.7-7.9

[1] Disease intensity was rated on a scale of 0 (no disease) to 9 (whole roots severely diseased).

Table 2. Intensity of bean diseases in 36 crops of field bean in Manitoba in 2000.

DISEASE	NO. FIELDS AFFECTED	DISEASE INTENSITY IN AFFECTED FIELDS[1]	
		Mean	Range
Bacterial blights	36	2.8	1.5-4.5
Anthracnose	8	2.4	1.0-3.5
White mold	2	10.0	10.0
Rust	1	1.5	1.5

[1] White mold was rated as percent plants infected; other diseases were rated on a scale of 0 (no disease) to 5 (whole plant severely diseased).

CROP: Field pea

LOCATION: Manitoba

NAME AND AGENCY:
A.G. Xue* and L. Yager
Agriculture and Agri-Food Canada Research Centre, Unit 100-101, Route 100,
Morden, Manitoba R6M 1Y5.
* Current address: Eastern Cereal and Oilseed Research Centre, Agriculture and Agri-Food Canada, Room 2091, K. W. Neatby Building, 960 Carling Avenue, Ottawa, Ontario, Canada K1A 0C6.

TITLE: DISEASES OF FIELD PEA IN MANITOBA IN 2000

METHODS: Crops of field pea were surveyed for foliar diseases at 23 different locations in Manitoba. The survey was conducted in the third week of July when the plants were at the pod-fill to early maturity stages. The crops surveyed were chosen at random from regions in south-west and south-central Manitoba, where most field pea is grown. Ten plants were sampled at each of three random sites for each crop surveyed. Diseases were identified by symptoms. Fusarium wilt and sclerotinia stem rot were rated as percentage of plants infected. The severity of other diseases observed was estimated using a scale of 0 (no disease) to 9 (whole plants severely diseased).

RESULTS AND COMMENTS: Six diseases were observed in the 23 fields surveyed (Table 1). Mycosphaerella blight (*Mycosphaerella pinodes*) was the most prevalent disease, observed in all fields surveyed. However, severe infection (Intensity >6.0) by mycosphaerella blight was observed in only two crops. Average yield reduction was estimated at less than 10%. Fusarium wilt (*Fusarium oxysporum* f. sp. *pisi*) was observed in 16 of the 23 fields surveyed, and was the second most prevalent disease. The mean incidence of fusarium wilt was less than 4% for all infested crops and the disease did not appear to cause significant yield reduction. Sclerotinia stem rot (*Sclerotinia sclerotiorum*) was observed in seven fields and infection ranged from 10 to 70%. The yield reduction in sclerotinia stem rot-infested crops was estimated at more than 10% on average. Other diseases including powdery mildew (*Erysiphe pisi*), bacterial blight (*Pseudomonas syringae* pv. *pisi*), and anthracnose (*Colletotrichum pisi*) were observed in two, one, and one of the crops, respectively. Severity of these diseases was low and did not appear to cause significant damage to the pea crops.

Powdery mildew was the most prevalent disease on pea in Manitoba in previous years. The lower level of powdery mildew in 2000 may be due to early seeding (before May 10), the greater use of resistant cultivars, and unfavorable weather conditions, or a combination of these factors.

Table 1. Intensity of foliar diseases in 23 crops of field pea in Manitoba in 2000.

DISEASE	NO. FIELDS AFFECTED	DISEASE INTENSITY IN AFFECTED FIELDS[1]	
		Mean	Range
Mycosphaerella blight	23	3.9	1.5-8.5
Fusarium wilt	16	3.1	2.0-4.0
Sclerotinia stem rot	7	24.3	10.0-70.0
Powdery mildew	2	2.8	1.0-4.5
Bacterial blight	1	3.0	3.0
Anthracnose	1	3	3

[1] Fusarium wilt and sclerotinia stem rot was rated as percent plants infected; other diseases were rated on a scale of 0 (no disease) to 9 (whole plant severely diseased).

TITLE: DISEASES OF FLAX IN MANITOBA AND SASKATCHEWAN IN 2000

METHODS: A total of 74 flax crops in southern Manitoba and 48 in central and eastern Saskatchewan was surveyed in 2000. Forty-five crops were surveyed during the third week in July, and 77 crops during the third and fourth week in August. Solin flax with low linolenic acid and yellow seed colour was distinguished in 10% of the crops surveyed in August, but linseed constituted 90% of the crops surveyed. Crops surveyed were selected at random along preplanned routes in the major areas of flax production. Each crop was sampled by two persons walking 100 m in opposite directions in the field following an "M" pattern. Diseases were identified by symptoms and the incidence and severity of each disease were recorded. Stand and vigour were rated on a scale of 1 to 5 (I = very good, and 5 = very poor).

In addition, 30 samples of flax plants were submitted for analysis to the Manitoba Agriculture and Food Crop Diagnostic Centre by agricultural representatives and growers.

RESULTS AND COMMENTS: Seventy-five percent of the flax crops surveyed in 2000 were rated very good for stand establishment, and 63% had very good vigour. Thirty-two percent of the crops surveyed were seeded late and were expected to be late for maturity and harvesting. Growing conditions were generally good except for abnormally wet conditions towards the end of August in southern Manitoba and eastern Saskatchewan, which resulted in heavy lodging in several crops and noticeable amounts of dark brown and black seed.

Pasmo (*Septoria linicola*) was observed in 86% of the crops surveyed (Table 1). The prevalence and severity of pasmo in 2000 were similar to 1999 but higher than in previous years (1, 2), due perhaps to the relatively wet weather during the second half of the growing season. In the infested crops, pasmo incidence ranged from 1% to 100% infected plants, and severity ranged from 1% to >60% stem and leaf area affected. Twenty-six percent of the crops had >60% plants severely infected with pasmo.

Heavily lodged plants were observed in 28% of crops, and traces to 80% of the plant area affected by *Alternaria* and other saprophytic fungi were observed in lodged crops. Frequent visits to some flax fields in southern Manitoba towards the end of the season revealed higher levels of pasmo and *Alternaria* infections than those observed in August.

Flax stems infected by *Sclerotinia sclerotiorum* were observed in only three crops in 2000 in comparison to 14 crops in 1999 (1). Typical symptoms were white bleached and shredded stems and tiny cylindrical sclerotia inside infected stems. The *Sclerotinia* infections were only observed in heavily lodged flax.

Root infections and fusarium wilt (*Fusarium oxysporum f.sp. lini*) were observed in 54% of flax crops in 2000 in comparison to 93% and 86% of crops, respectively in 1999 and 1998 (1, 2). Incidence of

fusarium wilt ranged from trace to 10%, except for a few crops in Manitoba and Saskatchewan where fusarium wilt incidence ranged from 20-30%.

Powdery mildew (*Oidium lini*) was observed again in 2000 in 10% of the crops surveyed with a severity range from trace to 40% leaf area affected. The incidence and severity of this disease were low in 2000 in spite of the sharp increases in the last three years since it was first reported in western Canada (1, 2). Most of the flax crops affected by powdery mildew were near Regina, Grenfell, Melfort, and Yorkton in Saskatchewan, and near Portage la Prairie and south central areas in Manitoba.
Traces to 5% affected plants were observed with aster yellows (phytoplasma) in 11% of the flax crops in 2000. The incidence and severity of aster yellows in 2000 were lower than in 1999 when the severity of this disease was higher than in any of the last 10 years (1).

Rust (*Melampsora lini*) was not observed in any of the 122 crops surveyed, nor in the rust-differential flax nurseries planted at Morden and at Portage la Prairie.

Of the 30 flax samples submitted to the Manitoba Agriculture and Food Crop Diagnostic Centre, one was affected by pasmo, two affected by fusarium wilt/root rot (*Fusarium oxysporum f.sp. lini* and other *Fusarium* spp.), one affected by seedling blight *(Rhizoctonia spp*), and two with black seed (*Alternaria spp.).* In addition to diseases, 16 samples were affected by herbicide injury, two samples by nutrient deficiencies, and six samples by various environmental factors.

ACKNOWLEDGEMENTS: The assistance of Lawrence Wiebe and Maurice Penner in conducting this survey is gratefully acknowledged.

TITLE: SEED-BORNE PATHOGENS OF LENTIL IN SASKATCHEWAN IN 2000

METHODS: The results of agar plate tests conducted by four Saskatchewan companies on seed samples from the 2000 crop were summarized. The tests were conducted mainly to detect the pathogens causing ascochyta blight *(Didymella [Ascochyt*a] *lenti*s), anthracnose *(Colletotrichum truncatu*m), grey mould and seedling blight *(Botrytis cinere*a) and sclerotinia stem and pod rot *(Sclerotinia sclerotiorum*). Not all samples were tested for *Colletotrichu*m, *Botrytis* and *Sclerotinia* but all were tested for *Ascochyt*a. Figures for *A. lentis* and *B. cinerea* were classified according to crop districts [CD] of Saskatchewan (Fig. 1). However, this was not done for *C. truncatum* and *S. sclerotiorum* because infection levels are generally so low that comparisons of means would be valueless.

It was unknown which of the seed samples came from lentil crops that had been treated with registered fungicides. Bravo (a.i. chlorothalonil) is widely used as a foliar protectant against ascochyta blight and anthracnose, while Crown (a.i. thiabendazole + carbathiin) is often used as a seed treatment against seed-borne *Ascochyta* and *Botryti*s. This was the first year in which the use of new ascochyta-resistant lentil cultivars was widespread. Therefore, mean provincial infection levels for ascochyta in seed were calculated separately for resistant and susceptible cultivars, when the information was available.

RESULTS AND COMMENTS: In most areas of Saskatchewan the growing season started with relatively dry conditions that resulted in early completion of seeding in May. From June to early August rainfall amounts varied from about 50% to 200% of normal in different crop districts, with the wettest conditions generally in the northeast, southeast and south central areas. In late August good harvest weather prevailed throughout the province, but in early September rain and warm humid weather caused deterioration of crop quality in many areas. The average provincial lentil yield was similar to the 10-year average, but about 8% below that in 1999.

By mid-December nearly 1200 lentil seed samples had been tested by the four companies. The 10% increase over 1999 in lentil samples tested (1) was probably due to a substantial increase in acreage. Mean levels of seed-borne *Ascochyta* varied among crop districts (Table 1), but were not necessarily highest in districts which received the highest total rainfall in June and July. The highest value was 41% in a sample from CD 2A.

On a provincial basis the mean level of seed infection was 2.5%, while 34% of samples tested 0% ascochyta. The corresponding figures for 1999 were 3.1% and 17%. While this indicates a reduction in levels of ascochyta blight from 1999 to 2000, the reason is probably related more to the change in lentil cultivars than to weather. Approximately 25% of samples tested in 2000 were new ascochyta-resistant cultivars [CDC Glamis, CDC Grandora, CDC Milestone, CDC Redcap, CDC Redwing, CDC Robin, CDC

Sovereign, CDC Vantage, 997-5R]. The mean *Ascochyta* seed infection in these cultivars was 0.4%. About 50% of all samples tested were known susceptible cultivars [CDC Richlea, Crimson, Eston, French Green and Laird]. In these, the mean *Ascochyta* seed infection was 3.3%. In the remaining samples, for which no cultivar was specified, but which were probably mostly susceptible types, the mean *Ascochyta* seed infection was 2.9%. The values of 3.3% and 2.9% are probably the most appropriate to compare with figures for the previous 3 years (1,2,3).

Botrytis was detected in 80% of all samples tested. The corresponding percentages were 69% [erroneously reported as 31% in reference 1) in 1999 and 73% in 1998 (2). The mean infection level was 2.3%, compared with 0.7% in 1999 and 0.3% in 1998. Thus, there was a substantial increase in prevalence and incidence of seed infection compared with the two previous years. The highest level of seed infection in 2000 was 19.5%.

*Colletotrichum truncatu*m, which is not a highly seed-borne pathogen, was detected in 7.8% of the samples tested, slightly lower than in the past several years. Most records were from CD 2B, 3A-N, 3B-N and 6B; however other records from CD 2A, 3A-S, 3B-S, 5A, 5B, 6A, 8A and 9A confirm that anthracnose has now spread to all major areas of lentil production in Saskatchewan. The highest level of seed infection detected in 2000 was 5.0%.

As in 1999 (1), *S. sclerotiorum* was commonly isolated from lentil seed but at low levels. This probably reflects the cool wet weather in many areas in July and an increasing number of broad-leaved crops in rotations in the major lentil-producing regions.

TITLE: SEED-BORNE PATHOGENS OF PEA IN SASKATCHEWAN IN 2000

METHODS: The results of agar plate tests conducted by four Saskatchewan companies on seed samples from the 2000 crop were summarized. The tests were conducted mainly to detect the pathogens causing ascochyta blights (*Mycosphaerella* [*Ascochyta*] *pinodes* and *A. pisi*), botrytis blight (*Botrytis cinerea*) and sclerotinia stem and pod rot (*Sclerotinia sclerotiorum*). Not all samples were tested for *Botrytis* and *Sclerotinia* but all were tested for the ascochyta blight pathogens. Figures for *Ascochyta* spp. and *B. cinerea* were classified according to crop districts [CD] of Saskatchewan (1). However, this was not done for *S. sclerotiorum* because infection levels are generally so low that comparisons of means would be valueless.

RESULTS AND COMMENTS: In most areas of Saskatchewan the growing season started with relatively dry conditions that resulted in early completion of seeding in May. From June to early August rainfall amounts varied from about 50% to 200% of normal in different crop districts, with the wettest conditions generally in the northeast, southeast and south central areas. Frost in a large area of east-central Saskatchewan on July 16 caused severe damage and yield loss in many pea crops. In late August good harvest weather prevailed throughout the province, but in early September rain and warm humid weather caused deterioration of crop quality in areas where harvest was not complete. The average provincial pea yield was 10% greater than the 10-year average, but about 17% below the exceptional mean yield of 1999 (2).

By mid-December nearly 500 pea seed samples had been tested by the four companies. Mean levels of seed-borne *Ascochyta* spp. varied among crop districts (Table 1), with the highest levels in the northern crop districts (CD 8 and 9) where there is the longest history of pea growing. The maximum recorded value was 24.5% in two samples, one from CD 6A and one from CD 8B.

On a provincial basis mean seed infection was 3.1% and the percentage of samples in which no infection was detected was 24%. These values were 25% lower and 40% higher, respectively, than corresponding values for 1999 (2). However, mean provincial seed infection levels were still considerably higher than those recorded 1998 and 1997 (3,4).

Botrytis was detected in 28% of pea samples tested compared with 35% in 1999 (2). However, the mean seed infection level was 0.3% for both years. The highest mean seed infection levels were in CD 2B, 7B, 8A, 8B and 9B (Table 1) and the highest individual value recorded was 5% in CD 8B. Generally *Botrytis* was not a problem on pea crops in Saskatchewan in 2000. *Sclerotinia sclerotiorum* was isolated from less than 30% of pea seed samples in 2000 and, in these, most commonly at a level of 0.5 or 1.0%.

TITLE: DISEASES OF SOYBEAN IN ONTARIO AND ESTIMATED YIELD LOSSES, 1994,1996-2000

INTRODUCTION: Soybean production has increased dramatically in Ontario during the past 30 years. The increase has occurred in new production areas in central and eastern Ontario in addition to more frequent cropping of soybean in southwestern Ontario. Cultural practices such as tillage have also changed during recent years. Increased production has contributed to an increase in the frequency and severity of soybean diseases. Reduced tillage may be economical but may contribute to increased disease severity by reducing soil temperatures and increasing soil moisture at planting.

There has been no general disease loss survey of soybean in Ontario. Such a survey would be difficult with over 800 thousand ha of soybean in Ontario in 2000. However, with large acreage crops, it is useful to estimate losses for the following reasons: 1) to document the presence of diseases, 2) to priorize research on disease management and 3) to provide direction to public and private soybean breeders in developing disease resistance. Therefore, disease loss estimates were developed as a guide to those interested in Ontario soybean diseases.

METHODS: Disease loss estimates were derived from non-formal surveys, grower samples submitted for diagnosis, discussion with extension agents, crop consultants, growers and provincial authorities. Observations of soybean diseases are made during the annual field plot tour of the Ontario Oil and Protein Seed Crop Committee which involves visits in all soybean production areas of Ontario. The losses should be considered as only very general conservative estimates. It should also be noted that although some mean Ontario values are minimal, losses can be severe on an individual field, farm or region basis.

RESULTS AND COMMENTS: Disease loss estimates for 1994 (Wrather et al., 1997) and 1996 to 2000 are presented in Table 1. Bacterial diseases (bacterial blight [*Pseudomonas savastanoi* pv. *glycinea*] and wildfire [*Pseudomonas syringae* pv. *tabaci*]) are found in most soybean production areas but are not considered to cause economic losses. Diseases caused by fungi are commonly observed and can be severe. Seedling diseases caused by *Pythium* sp., *Fusarium* spp., *Rhizoctonia solani*, *Phomopsis* sp. and *Phytophthora sojae* occur in cool wet weather. The incidence of each pathogen may vary with soil type and temperature. In 2000, seedling disease was severe because of cool, wet weather. Sclerotinia stem rot (*Sclerotinia sclerotiorum*) has been a major problem in recent years in Ontario. The severity of sclerotinia stem rot increases during cool, wet weather in the period from pod fill to maturity and therefore the severity changes annually. The consistently important disease, phytophthora root rot is caused by *Phytophthora sojae*. Although soybean cultivars in Ontario are tolerant or resistant to this disease, isolates of the fungus with novel patterns of virulence continue to develop. The fungus is found in all soil types but most losses occur on poorly drained, fine textured soil. Sudden death syndrome (SDS) (*Fusarium solani* f. sp. *glycinea*) has increased in frequency since symptoms of the disease were first noted in 1993 (Anderson and Tenuta, 1998). The disease is found on sandy loam soils in association with infestations of soybean cyst nematode. The disease has become permanently

established in some fields and losses occur each year. Fusarium root rot and wilt (*Fusarium solani*, *F. oxysporum*) has increased in severity over the survey period. The disease occurs in hot weather following periods of heavy rain prior to pod set. It is found in all growing regions and is common in Eastern Ontario.

Rhizoctonia root rot (*Rhizoctonia solani*) may occur at all stages of plant growth but it is frequently observed in July during flowering. A typical zonate canker with alternating dark and light bands develops on the lower stem. The disease is frequently associated with high organic matter and hot conditions following high rainfall. Northern stem canker (*Diaporthe phaseolorum* var. *caulivora*) has become more common recently. The incidence of this disease is higher under minimum tillage and may affect soybean prior to flowering under hot humid conditions. Phomopsis seed rot (*Phomopsis longicola*) and pod and stem blight (*Diaporthe phaseolorum* var. *sojae*) are very weather dependent. Seed rot occurs more frequently with warm wet weather prior to harvest. Charcoal rot (*Macrophomina phaseolina*) and brown stem rot (*Phialophora gregata*) appear to be increasing in importance, especially under hot dry conditions in August. Brown spot (*Septoria glycines*) downy mildew (*Peronospora manchurica*), purple stain (*Cercospora kikuchii*), powdery mildew (*Microsphaera diffusa*) and frogeye leafspot (*Cercospora sojina*) can be observed in most seasons but rarely cause yield problems. Brown spot is becoming more severe especially if plants are under moisture or nutritional stress.

Viruses (soybean mosaic virus, tobacco ringspot virus) seldom cause significant yield losses in growers' fields; however, disease symptoms such as pod abortion and green stem are becoming more common. In 2000 random samples of green stem plants tested for bean pod mottle virus proved negative.

The single most important pathogen of soybean in Ontario is soybean cyst nematode (*Heterodera glycines*) (SCN). Since it was first found in 1987 (Anderson et al., 1988), the nematode has increased in distribution and abundance. Fortunately, SCN resistant cultivars are available and yield losses are beginning to decline in areas with a history of SCN. The nematode continues to spread to new areas to the east and it is probable that SCN will remain the most important pathogen of soybean in Ontario for a number of years. Yield losses of 20-40% in individual fields have been documented. Foliar symptoms may or may not be evident in infested fields.

CONCLUSIONS: We expect soybean disease pressure to continue to increase in Ontario with decreased crop rotation. SCN will increase in importance as the pest spreads to new areas of the province. Although resistant cultivars reduce yield losses, soil sampling and crop inspection are needed to identify the pest. The increase in pre and post emergent seedling diseases may be reduced in the future with an increased emphasis by industry on new seed treatments. The need for effective broad spectrum seed treatments is still high.

Further research needs to be done on the influence of reduced tillage practices on disease incidence. In Ontario, residue-borne soybean diseases are increasing as a result of adoption by growers of good conservation soil management. A balance between soil management practices and disease control must be found. Many early-season diseases are more severe when seed vigour is low. Both public and private soybean breeders need to continue to develop cultivars with high seedling vigour and new sources of resistance to the important soybean diseases in Ontario.

CROP: Sugar beet

LOCATION: Southern Alberta

NAME AND AGENCY:
S. D. Bardin and H.C. Huang
Agriculture and Agri-Food Canada
Research Centre, P.O. Box 3000, Lethbridge, Alberta T1J 4B1

TITLE: SURVEY OF DAMPING-OFF DISEASES OF SUGAR BEET IN SOUTHERN ALBERTA in 2000

INTRODUCTION: With a processing plant in Taber, southern Alberta is the only area of sugar beet production in Canada. The area contracted for sugar beet production has increased from 12,150 ha in 1986 to 18,220 ha in 1999 with root yield reaching 850,000 tonnes in 1999 (Chaudhary 1998). With the expansion of the sugar beet processing plant in 1998, sugar beet production is likely to expand further in this area. Sugar beet is an important crop for rotation with cereals and legumes and for crop diversification in western Canada. Nevertheless, it is highly susceptible to damping-off pathogens such as *Pythium* sp. "group G", which is widespread in southern Alberta (Huang et al. 1992). A survey of damping-off diseases of sugar beet in southern Alberta was conducted during the growing season of 2000.

METHODS: Twenty-six crops of sugar beet were surveyed for damping-off diseases between May 16 and June 7. The survey covered the sugar beet growing area of southern Alberta, from Picture Butte to Bow Island and south to Foremost. Emergence within a field was estimated by counting the number of seedlings at 9 sites. The sites were located in three rows, randomly selected, approximately 30 m apart from one another. Each row had three sites, 4.5 m in length, that were 20 m apart in the row. Due to the precision seeding used in commercial production of sugar beet in Alberta (one seed per 15 cm), a 4.5 m site consisted of 30 plants. Percent emergence was calculated by dividing the number of seedlings by 30 and multiplying by 100. Soil samples were collected from the surveyed fields and tested for incidence of damping-off pathogens of sugar beet in the growth chamber. Three pots filled with soil from each surveyed crop were planted with seeds of sugar beet c.v. HM Bergen (five seeds per pot). The pots were watered and put in propagator trays to produce high moisture condition for the development of the disease. The propagator trays were kept in a growth cabinet under controlled light and temperature conditions (16 h day/8 h night; 20°C/15°C). The number of plants emerged was recorded after 14 days and the percent emergence was calculated for each crop. Non-germinated seeds were collected, washed in sterile water, surface sterilized in 70% ethanol for 2 min, plated on potato dextrose agar (PDA) and incubated for 3 to 5 days. Fungi isolated from the seeds were purified on PDA and the genus of each fungus isolated was determined based on morphological characteristics.

RESULTS and DISCUSSION: The field survey showed that seedling emergence varied among crops. Of the 26 crops surveyed, seedling emergence was less than 50% in four crops, 50 to 65% in 12 crops, 66 to 80% in seven crops and over 80% in three crops (Table 1). The four crops that showed emergence lower than 50% were surveyed on May 16 at which time seedling emergence may not have been complete, due to the long emergence period of sugar beet. Early June is therefore the best period to assess seedling emergence in sugar beet seeds. The relationship between seedling emergence in the field and disease incidence was assessed by testing the soils collected in growth chamber experiments.

Results of soil testing showed that seedling emergence in soil collected from each field surveyed ranged from 26 to 94%. Severe disease was observed in six soils (emergence less than 60%), while 11 soils had low disease (emergence of 61-80%) and nine soils had no disease (emergence over 80%) (data not shown). Severely diseased crops therefore account for 23 % of the fields surveyed. When comparing

indoor and outdoor seedling emergence, four of the soils rated as having severe disease incidence had emergence in the field around 63% (Table 1). One of the soils with 34% seedling emergence in the indoor experiment also showed very low emergence in the field (36%) (Table 1). Another soil that showed low emergence in the indoor experiment (46%) had an emergence level of 72% in the field (Table 1). *Pythium* sp., likely *Pythium ultimum* "group G" that is widespread in sugar beet in southern Alberta (H.C. Huang, unpublished data), was isolated from non-germinated seeds from five of the fields rated as severely diseased. The fungus *Rhizoctonia solani* was found in two of the crops, with field emergence of 55% and 68%. Both soils had a 74% seedling emergence in the indoor experiment. These data suggest that *Pythium* is the main cause of poor stands of sugar beet in southern Alberta, while *Rhizoctonia* is of minor importance. High disease pressure from a pathogen such as *Pythium* sp. may be due to field history or crop management such as growing sugar beet in rotation with other susceptible host crops, like canola, safflower and dry pea.

TITLE: DISEASES OF SUNFLOWER IN MANITOBA IN 2000

METHODS: Forty-nine sunflower crops in southern Manitoba and three crops in southeastern Saskatchewan were surveyed in 2000. Ninety percent of the crops were confectionery hybrids and 10% were oilseed hybrids. Eight crops were surveyed during the last week of July, and 44 crops during the last week of August. Crops were surveyed along preplanned routes in the major areas of sunflower production. Each crop was sampled by two persons walking 100 m in opposite directions in the field following an "M" pattern. Diseases were identified by symptoms and the percent incidence of downy mildew (*Plasmopara halstedii*), sclerotinia wilt or head and stem infections (*Sclerotinia sclerotiorum*), rhizopus head rot (*Rhizopus* spp.), and verticillium wilt (*Verticillium dahliae*) were estimated. Disease severity for rust (*Puccinia helianthi*), leaf spots (*Septoria helianthi* and *Alternaria* spp.), powdery mildew (*Erysiphe cichoracearum*) and stem infections (*Phoma* spp. *& Phomopsis* spp.) were measured as percent leaf and stem area infected. A disease index was calculated for each disease in every crop based on disease incidence or disease severity (Table 1).

In addition, 31 samples of sunflower plants were submitted for analysis to the Manitoba Agriculture and Food Crop Diagnostic Centre by agricultural representatives and growers.

RESULTS AND COMMENTS: Seventy percent of the sunflower crops surveyed in 2000 had excellent to good stands and vigour, and only 30% had moderate stands and vigour. Forty-three percent of the crops were seeded late and were expected to mature very late. Growing conditions were generally good except for abnormally wet conditions at maturity time which resulted in high incidence of head rot in several crops. Traces to 5% infestation of sunflower midge (*Contarinia schulzi*) were observed in several crops in the Red River Valley, however, the severity of infestation was extremely low in comparison to the last two years (1, 2).

Sclerotinia diseases were more prevalent in 1999 than in 1998 (1). Sclerotinia wilt/basal stem infection was present in 67% of the crops surveyed, with incidence ranging from trace to 15% infected plants (Table 1). Sclerotinia head rot and mid-stem breakage caused by ascospore infections were present in 65% of the crops surveyed with incidence ranging from trace to 15% infected plants. Visits to some sunflower crops in southern Manitoba towards the end of September revealed higher incidences of head rot than observed during the August survey due, perhaps, to frequent rainfall in late August.

Verticillium wilt was present in 54% of the crops surveyed, with incidence ranging from trace to 30% infected plants (Table 1). The prevalence and incidence of verticillium wilt in 2000 was lower than in 1999 (1) in spite of the increased acreage of confectionery hybrids (90% of total acreage).

Downy mildew was observed in 20% of the crops surveyed but the incidence was very low (trace to 1%) in most crops (Table 1). This is the third consecutive year where dry soil conditions and above normal soil temperatures at the seedling stage may have contributed to low incidence of downy mildew.

Rust was present in 40% of the crops surveyed, with severity ranging from trace to 5% leaf area affected in two-thirds of the crops and up to 60% leaf area affected in one-third of the crops (Table 1). Although the incidence of rust was lower in 2000 than in 1999, the severity in most crops surveyed was higher in 2000 than in 1999 (1, 2).

Traces to 10% leaf area covered by spots caused by *Septoria helianthi* and *Alternaria* spp. were observed in 30% of crops surveyed in 2000. Phoma stem lesions were present in 10% of the crops at trace to 5% stem area affected (Table 1). Trace levels of rhizopus head rot were observed in 10% of the crops. Trace levels of phomopsis stem lesions were observed in a few crops. Traces to 5% leaf area affected by powdery mildew were observed in two crops towards the end of the season.

Of the 31samples submitted to the Manitoba Agriculture and Food Crop Diagnostic Centre, three samples were identified as root rot caused by *Fusarium* spp., two phoma black stem caused by *Phoma* spp., one downy mildew, one aster yellows caused by a phytoplasma, one damping off caused by *Pythium* spp, and one head rot caused by *Sclerotinia sclerotiorum.* In addition to diseases, three samples were affected by insects, four by environmental and physiological factors, and 15 were affected by herbicide injury.

ACKNOWLEDGEMENTS: The assistance of Lawrence Wiebe and Maurice Penner in conducting this survey is gratefully acknowledged.

TITLE: CROSS-CANADA POTATO LATE BLIGHT SURVEY IN 1999

METHODS: In 1999, 93 samples of potato and tomato suspected of having late blight were received from all provinces. Isolates of *Phytophthora infestans* Mont. (de Bary) were prepared in pure culture and studied for mating type and metalaxyl sensitivity, according to Peters (3) and Peters et al. (4), and glucose phosphate isomerase (*Gpi*) allozyme patterns according to Goodwin et al. (2). Metalaxyl sensitivity was based on 100 µg/ml metalaxyl in the medium, according to Peters (3).

RESULTS: The recovery of active late blight from samples was slightly lower (75%) than in 1998 (81%) (1). About 60%, 57%, 59%, and 89% of the samples received from Newfoundland (NF), Manitoba (MB), Prince Edward Island (PEI), and British Columbia (BC), respectively, were infected with *P. infestans* (Table 1). Only one, two and three samples were sent from New Brunswick (NB), Quebec (PQ) and Ontario (ON), respectively, and they were all infected with late blight. The single samples sent from Alberta (AB) and Nova Scotia (NS) were free of the late blight pathogen. Many of the samples received were also infected by other fungi such as *Verticillium*, *Alternaria*, *Botrytis, Fusarium*, or *Rhizoctonia*. The A2 mating type has been found in all Canadian provinces from which infected samples were received, and represented about 71% of the total isolates obtained versus 29% for A1 (Table 1). The A1 mating type was found only in British Columbia. Regarding the genotypes, no US-1 (A1), US-6 (A1), or US-7 (A2) strains were found among the samples received in 1999. On the other hand the Gpi allozyme bandings characterizing genotypes US-10 (MB and PEI), US-11 (BC), and US-8 (BC, MB, NB, NF, ON, PEI, and PQ) were detected.

Among the 267 isolates tested for resistance to metalaxyl, 22% were sensitive (MS), 50% were moderately-resistant (MMR) and 28% were highly-resistant (MHR) (Table 1). In 1999, except in NF, there were more MMR than MS isolates in all provinces, and MHR isolates were found in BC, MB, NB, ON, PEI, and PQ. Among all the A1 isolates, about 1% were MS, 62% were MMR, and 37% were MHR. On the other hand, A2 isolates were about 29% MS, 52% MMR, and 19% MHR. These results clearly indicate an increase in resistance to metalaxyl as compared to 1997 and 1998, especially within US-8 genotype, and a variation in this marker within each genotype.

Thirty eight isolates (19 A1,US-11 and 19 A2,US-8) were tested for their physiologic races. In general, US-8 isolates showed more virulence gene complexity than US-11 isolates. While US-11 isolates could infect on average 2.7 potato differentials, US-8 isolates could infect on average six differentials. In addition, most of the US-11 isolates infected only up to five differentials, except for one isolate that infected seven differentials. In addition, 74% US-11 isolates did not infect more than four differentials. On the other hand, 34% of the US-8 isolates infected all of the ten tested differentials. In addition, only 26% US-8 isolates infected fewer than four differentials.

Thus, variation continues to occur in *P. infestans* populations causing potato late blight in Canada, especially in levels of resistance to metalaxyl. The cause of the changing nature of the pathogen populations and their impact on disease and its control require further study. Also, this year, we received tomato samples from BC, from which the A1 mating type was isolated. Since this plant can be a potential source of inoculum for potato, it is important to monitor tomato late blight in crops and home gardens across Canada.

[1] Samples were sent from nine Canadian provinces. BC= British Columbia, MB= Manitoba, NB= New Brunswick, NF= Newfoundland, ON= Ontario, PEI= Prince Edward Island, and PQ= Québec. No isolates could be retrieved from samples sent from Alberta (AB) and Nova Scotia (NS).

[2] Mating types were determined after confrontation of isolates with each of the known controls P1023A1 (A1), P1025A1 (A1), P1024B2(A2), and P1031B2(A2) on rye agar medium. Isolates forming oospores with the first two were designated A2, and those forming oospores with the latter two were designated A1.

[3] Resistance to metalaxyl was tested *in vitro* and was based on the relative growth of mycelium at 100 µg/ml *vs* 0 µg/ml of metalaxyl (MTXL) as follows: percent growth (pg) = 100 x (diameter of growth at 100 µg/ml MTXL minus 5 mm) / (diameter of growth at 0 µg/ml MTXL minus 5 mm). Diameter of growth was the mean of six measures. Each isolate was determined as metalaxyl-sensitive (MS) when pg < 10 %, metalaxyl-moderately resistant when 10 % < pg < 60 %, or metalaxyl-highly resistant (MHR) when pg > 60 %. The percentage is calculated separately for each mating type.

[4] 111 pure cultures were also sent for testing.

TITLE: **SURVEY OF BLUEBERRY SCORCH VIRUS IN HIGHBUSH BLUEBERRIES IN BRITISH COLUMBIA, 2000**

INTRODUCTION: In June 2000, Blueberry Scorch Virus (BlSV) was identified for the first time in British Columbia. The first finding was from mature 'Berkeley' highbush blueberry plants exhibiting extensive blossom blighting and dieback of young leaves and shoots. A week later, the virus was detected in the cultivars 'June' and 'Weymouth' located at a considerable distance from the infected 'Berkeley' field. A survey was undertaken to determine the distribution of BlSV in commercial blueberry fields across the Lower Mainland.

METHODS: In July and August 2000, 141 blueberry plants were sampled from 25 farms where growers or consultants reported suspicious symptoms. New leaf growth from branches exhibiting symptoms was used for testing, although some symptomless plants were also sampled. Two neighbouring fields were sampled more intensively in order to determine the field distribution. DAS-ELISA (Agdia Inc.) was used to detect BlSV. Samples were also tested for blueberry shock virus, which has not been detected in BC.

RESULTS AND COMMENTS: BlSV was detected in many different cultivars and ages of plants (Table 1), and it was present in most regions sampled across the Lower Mainland (Figure 1). BlSV was detected in both symptomatic and symptomless plants selected in two neighbouring fields (Figure 2), demonstrating that a lack of symptoms should not be used as an indicator for the absence of BlSV. Occasional symptom expression in cultivars reported to be symptomless in Washington State raises the possibility that the BlSV strain in BC is different from the BlSV in Washington State. Investigation is underway to determine if BC has the New Jersey (Sheep Pen Hill) strain, the Washington strain, or both strains.

The widespread distribution of BlSV was alarming. Research is urgently needed to understand the disease and its potential impact on BC blueberry production. All samples were negative for blueberry shock virus.

TITLE: SURVEY FOR FLAG LEAF SYMPTOMS OF POWDERY MILDEW IN GRAPE IN NIAGARA PENINSULA, ONTARIO, 1991-1994

INTRODUCTION AND METHODS: *Uncinula necator*, causal agent of powdery mildew of grapevine, has been reported to overwinter as dormant mycelium in buds and as cleistothecia lodged in trunk bark. Knowledge of the source of primary inoculum is important for making decisions regarding chemical control early in the growing season. Infections surviving in dormant shoots are expressed as "flag shoots" as early as bud break in most grape growing areas in the world. Sporulation can occur on these flag shoots almost immediately, providing a source of primary inoculum very early in the growing season. Ascosporic infections arising from inoculum overwintering in cleistothecia require specific environmental conditions for release of ascospores (0.25 mm rain and minimum of 10^{o}C). A survey for flag shoots was conducted when shoots were 15-25 cm in length (mid-June) in commercial vineyards in the Niagara Peninsula, 1991-1994. All or some of the following cultivars were present at each site and were sampled separately: Riesling, Chardonnay, S.V. 23-512, Gewurztraminer, Cabernet Sauvignon, Cabernet Franc. A total of 22, 24 23 and 21 sites were included in 1991, 1992, 1993 and 1994, respectively. At each site for each cultivar, all shoots on each of 100 randomly selected vines were examined for the presence of flag shoots.

RESULTS AND COMMENTS: No flag shoots were recorded at any of the sites in any cultivar over the 4-year period of the survey implying that flag shoots are not the source of primary inoculum for *U. necator* in the Niagara region. Similar findings have been reported in New York. (1)

TITLE / TITRE: OUTBREAK INVESTIGATION AND DETECTION SURVEY FOR PLUM POX POTYVIRUS IN 2000

INTRODUCTION: Plum pox is the most serious disease of plum, apricot and peach in Europe. It is caused by the plum pox virus (PPV). Different strains of the virus occur with variable host susceptibility and symptoms. Fruit quality, size and quantity are affected, often requiring removal of infected trees. Yield and overall economic losses have been catastrophic to plum and peach growers in many countries. On heavily infected trees, fruit can drop 20-30 days before the normal maturity date and fruit that remains on the tree may lack flavour and be low in sugar content. The main source of PPV is infected trees or budwood. The virus is spread locally by several species of aphids.

First identified in Bulgaria, plum pox is now reported in most European countries, in parts of Asia and northern Africa, and in South America (Chile). In October 1999, the D-strain of PPV was discovered on peaches grown in Adams County, Pennsylvania. This was the first report of PPV in North America and prompted the CFIA to initiate surveys in Canada in 2000, which are reported here.

METHODS: Initially, the survey targeted orchards which had been planted with material imported from Pennsylvania in the past 3-4 years. This material (all peach or nectarine) was distributed among seven growers, one of whom was in Nova Scotia with the remainder in the Niagara region. In blocks where the Pennsylvania material could be identified, all trees were sampled individually at 12 leaves per tree and each tree considered a separate sample. For a few blocks, the trees imported from Pennsylvania were inter-planted with existing trees and could not be specifically identified. In such cases, the blocks were composite sampled according to a systematic random sampling protocol. The starting point for sampling a block was chosen by randomly selecting the start tree from among the first four trees in one corner of the block. Each composite sample contained 12 leaves collected from a group of four consecutive trees in a row (3 leaves per tree). Twelve trees were then counted and skipped followed by the collection of another composite sample from the subsequent four trees. This pattern was continued throughout the entire block so that 25% of the trees were included in composite samples. The composite sampling protocol was the principal survey method used for the national detection survey which was implemented after the discovery of the first PPV positive.

A triple antibody sandwich (TAS-ELISA) was used as the main diagnostic method in the survey (monoclonal antibody: 5B-IVIA, Durvis s.I, Spain). Details of the methodology are described in the CFIA Centre for Plant Health test protocol TF0001-01. Samples were tested at three CFIA laboratories (Sidney, B.C., Charlottetown, P.E.I. and Nepean, Ontario). Sample preparation support was provided by laboratories of Agriculture and Agri-Food Canada in Summerland, British Columbia and Vineland, Ontario.

RESULTS AND COMMENTS: On June 23, 2000, the CFIA confirmed the presence of PPV in the town of Niagara-on-the-Lake, Ontario. PPV was discovered in three ‘Fantasia’ nectarine trees in two commercial orchard blocks owned by two different growers, located about 3 km apart. Laboratory testing by the CFIA’s Centre for Plant Health in Sidney, B.C. confirmed the virus was PPV strain-D.

A large-scale survey was implemented that included all the main stone fruit production areas in Canada. Cherries were excluded from the survey because they are not susceptible to the common strains of PPV. Table 1 summarizes the numbers of samples collected in each of the provinces involved. The majority of the samples were collected as part of a national PPV detection survey or from delimitation surveys around positive blocks using the composite method described above. In total, 70-100% of the commercial stone fruit production in Ontario was sampled in most of the production districts. In Quebec and Nova Scotia all commercial stone fruit orchards were sampled and in British Columbia about 30% of the production was randomly selected for inclusion in the survey. The figures in Table 1 also include a small number of individual-tree samples collected from all mother blocks across Canada, as well as a survey of 15% of the saleable PPV-susceptible nursery stock (fruit tree and ornamentals) within the Niagara region.

Table 1. PPV-susceptible *Prunus* samples collected in Canada in 2000.

PROVINCE	# SAMPLES[1]	# POSITIVE SITE LOCATIONS	# POSITIVE SAMPLES

TITLE: LITTLE CHERRY VIRUS SURVEY IN THE OKANAGAN AND KOOTENAY VALLEYS OF BRITISH COLUMBIA

METHODS: Cherry trees in the Okanagan and Kootenay Valleys of British Columbia were surveyed between 26 June and 23 August 2000 for little cherry disease virus (LCV). Orchards in districts with a history of the disease as well as other orchards with no known history were examined. Areas surveyed included Creston, Kelowna, Keremeos/Cawston, Naramata, Peachland, Oliver, Penticton, Summerland, Westbank, Winfield/Oyama and Vernon. Diagnosis of little cherry disease was based on a positive reaction in an ELISA test using antibody to the little cherry virus coat protein (Theilmann *et al.,* unpublished).

RESULTS AND COMMENTS: A total of 935 cherry trees were tested from orchards and residential properties. One-hundred and two trees tested positive for little cherry virus (10.9%), with 17 positives in Creston (12.2% of samples collected in Creston) and 85 positives in Penticton (16% of samples collected in Penticton). All Okanagan positives were in the Penticton area. One orchard in Penticton with a long history (30+ years) of LCV was intensively surveyed. Each tree was sampled individually. Of the 349 trees tested, 38 were positive (10.9%). Positive samples showed a clustered pattern, indicating a slow rate of spread.

TITLE/TITRE: PATHOGENIC FUNGAL SPECIES ON BALSAM FIR IN SOUTHERN QUEBEC

METHODS: The incidence of *Abies balsamea* (L.) Mill. (Balsam Fir) diseases was assessed in four groups of three trees with symptomatic branches (branch and needle necrosis and needle cast) in the Sherbrooke region, Québec, in 1999. Two small branches (30 cm long) were collected randomly from each tree group and used for disease assessment, pathogen isolation on agar media (potato dextrose agar and malt agar) and fungus species identification. Diseases were grouped by their isolation frequency, on the following scale : +, occasionally present (1-10%), ++ frequent (10-25%) and +++, very frequent (>25%).

RESULTS AND COMMENTS: Results are presented in Table 1. Of 13 identified fungal species, seven (54%) have not been reported previously on *A. balsamea* in Quebec (SPPQ/QSPP, 1996). The needle pathogens *Cytospora friesii*, *Phaeocryptopus nudus* and *Phyllosticta* sp. had the largest incidence (>25%). Furthermore, *Fusicoccum abietinum* dominated (10-25%) on buds and twigs and the rust pathogen *Melampsorella caryophyllacearum* was frequently found (10-25%) causing systemic brooms. Other fungal species were occasionally present, including *Leptomelanconium abietis* on chlorotic needles recently described by Vujanovic and St-Arnaud (2001).

TITLE / TITRE: DISTRIBUTION OF BUTTERNUT CANKER *(SIROCOCCUS CLAVIGIGNENTI-JUGLANDACEARU*M) IN EASTERN CANADA

INTRODUCTION: Butternut *(Juglans cinerea* L.) in Canada and the United States is endangered by butternut canker disease. Infection by the fungus *Sirococcus clavigignenti-juglandacearum* N.B. Nair, Kostichka & Kuntz, causes branch and stem cankers that can result in severe damage to the tree and often whole tree mortality. It is not known how long this disease has existed in North America, however it isbelieved to have been introduced (Furnier et al 1999). It was first reported from Wisconsin in 1967, but the causal agent was not described until 1979. In Canada, butternut canker was first collected in Quebec in 1990 (Innes and Rainville 1996), and then in Ontario in 1991 (Davis et al 1992), and in New Brunswick in 1997 (Harrison et al. 1998). It is known from the aging of cankers that the disease has been present in Ontario for at least 20 years. In 1990, the US Forest Service listed butternut as a sensitive species in the United States, and in most states where butternut occurs it is listed as a species of concern, largely due to this canker disease. The following reports on the distribution of this disease across eastern Canada.

METHODS: Data were collected from routine surveys of hardwoods by the Canadian Forest Service in Ontario and New Brunswick, and the Ministry of Natural Resources in Quebec. Butternut is not a very abundant tree species but occurs in small clumps or as single trees in association with other hardwoods. Because of this low density of potential host trees standard survey methodology utilizing transects could not be applied. Field technicians sought out known areas of butternut and conducted, in many instances, single tree evaluations. Locations where dead or dying trees were detected were sampled and routine isolation procedures were used to confirm the presence of *S. clavigignenti-juglandacearu*m. Data were compiled from the various jurisdictions and mapped using a geographic information system.

RESULTS AND DISCUSSION: The natural range of butternut extends throughout the northern eastern United States and the southern portion of eastern Canada. In Canada this tree species is found as scattered trees, or in small groups among other hardwoods in the deciduous forest region, the southeastern portion of the Great Lakes-St. Lawrence forest region and the western section of the Acadian forest region, from Ontario to New Brunswick (Figure 1). Ecologically, butternut is an important source of wildlife mast, especially in the northern part of its range where walnut is not present.

Butternut canker is currently known to exist throughout the range of butternut in Ontario and Quebec, with limited distribution in New Brunswick (Figure 1). The most obvious symptoms of the disease are elongated, sunken cankers on the bark (Figure 2). These cankers are frequently associated with wounds, but also with leaf and bud scars. During the spring and early summer, an inky-black fluid exudes from cracks in the canker. In the summer, the cankers appear as sooty black patches, often with whitish margins. The cambium layer beneath and surrounding the canker is dark-brown to black in color and dead. Cankers are perennial, and bordered by successive layers of callus tissue. Infection often originates in the lower crown and spreads downward as spores from the cankers are washed by rain along the branches and main stem.

Other members of the walnut family (Juglandaceae) also show some susceptibility to the pathogen when inoculated artificially. In Quebec, seedlings of black walnut *(Juglans nigra* L.) infected with the disease have been reported from tree nurseries. However, damage to black walnut is limited to small branch cankers, and severe infections on black walnut in forests or plantations have not been observed to date. Nevertheless, studies in Quebec have shown that the fungus is associated with the fruits of black walnut and butternut and the disease can be transported to new sites on the fruit (Innes 1998).

TITLE / TITRE : LE CHANCRE FUSARIEN SUR LE CHÊNE ROUGE (*QUERCUS RUBRA*) AU QUEBEC EN 1999 ET 2000

INTRODUCTION ET METHODES: On retrouve, dans le sud du Québec, plusieurs anciennes terres agricoles abandonnées. Le reboisement de ces terres se fait fréquemment par la plantation de *Quercus rubra* L. et *Q. macrocarpa* Michx. après préparation du terrain (Cogliastro et al. 1997). Nous avons récemment signalé dans la revue Plant Disease, l'apparition du *Fusarium solani* dans une plantation de chêne rouge de Cazaville (Vujanovic *et al.*, 1999). *Fusarium solani* cause des chancres annuels sur le tronc et les branches ainsi que le dépérissement d'une partie de la couronne. C'est la première mention de l'apparition des symptômes dus au fusariose sur les chênes rouges au Québec et au Canada. Auparavant, *Fusarium* n'a été signalé que sur les chênes rouges et noirs de la section LOBATAE: *Q. nuttallii* E.J. Palm. , *Q. rubra* L., *Q. phellos* L., *Q. nigra* L. de la côte est américaine (Sinclair 1993). Son apparition y a eu un impact négatif sur la production commerciale du chêne (Dochinger 1967). En Europe, le champignon isolé à partir des chênes atteints avait un très haut niveau de pathogénécité et de phyto-toxicité *in vitro* sur les semis de chênes (Ragazzi 1993).

Afin d'établir et d'estimer le rôle de la diversité des pathogènes dans la symptomatologie du chancre et du dépérissement du feuillage, quatre méthodes ont été appliquées:
Deux méthodes pour le chancre: i) Isolation des souches des parties du chancre sur les milieux d'agar (potato dextrose agar, malt agar) et ii) stimulation de l'exposition des souches, dans une chambre humide, (formation de sporodochie dans le cas de *Fusarium*);
Deux méthodes pour le dépérissement du feuillage: *i)* trempage du bois attaqué au niveau du système vasculaire (nécrose) dans l'eau en barbotage avec la présence de bouture stérile de chêne rouge et *ii)* passage du mycélium du pathogène vers des pièces de bois stériles insérées à l'intérieur de parties de bois symptomatique.

RESULTATS ET COMMENTAIRES : La maladie a été observée chez les arbres âgés de onze ans (semis 2+0 plantés en 1989). Deux modes d'action de *Fusarium* (pathogénicité et toxicité) se caractérisent avec des symptômes de chancre sur les tiges et les branches et de flétrissement des feuilles et des rameaux. On y a observé des symptômes chez plus de 50% des arbres, dont 25% des individus avaient des dommages jusqu'à 3m de hauteur de fût en 1999 et 27% en 2000. En 2000, le taux d'infection a été plus élevé (34%) dans des parcelles qui ont subi des traitements (paillis de plastique ou herbicide glyphosate) en comparaison avec le témoin (Table 1.). La maladie pourrait s'étendre et menacer la production commerciale du chêne. Parmi les autres pathogènes qui causent les chancres et les symptômes d'anthracnose, nous avons isolé occasionnellement (1% des échantillons) les espèces microfongiques (micromycètes) : *Apiognomonia*, *Botryosphaeria*, *Phomopsis* et *Valsa*.

À cause des connaissances incomplètes concernant les formes et les variétés de *Fusarium solani*, espèce complexe (O'Donnell, 2000), et en tenant compte de la diversité de la microflore parasite

impliqué, il semble difficile de diagnostiquer et de pronostiquer le développement de la pathologie du chêne rouge dans les régions écologiques du Québec et du Canada. L'apparition d'un tel problème phytosanitaire en plantation de feuillus souligne l'importance de définir et d'adopter des mesures de précaution.

Nous proposons des travaux de recherche qui permettraient de mieux caractériser le champignon. Ces connaissances seraient à la base d'un futur programme visant à circonscrire l'aire de répartition du parasite et à examiner la résistance de différentes provenances québécoises et canadiennes de chêne rouge. Il est proposé de caractériser la virulence, la toxicité et le profil génétique de *Fusarium solani*, en cinq étapes:
Plusieurs isolats pour représenter la diversité de la population : isoler des souches des plantes symptomatiques et asymptomatiques et sélectionner les isolats sur la base de critères morphologiques et culturaux; une souche américaine serait également incluse aux tests de virulence et de toxicité;

Virulence et toxicité des isolats: étudier la virulence et la toxicité des souches isolées, afin de déterminer la ou les souches responsables des symptômes de chancre et d'anthracnose *in situ*;

Profil génétique des isolats: analyser le profil génétique des souches isolées afin de préciser l'identification des isolats et de permettre la reconnaissance ultérieure à l'aide de sondes moléculaires spécifiques;

Comparaison: notre souche avec d'autres au Canada et avec souches des États-Unis; et

Croisement des connaissances: virulence-toxicité-génétique.

TITLE: STATUS OF EUROPEAN LARCH CANKER IN ATLANTIC CANADA 2000

METHODS: Field surveys for European larch canker (*Lachnellula willkommii*) were conducted in selected forest stands and plantations with a native or exotic larch (*Larix* spp.) component at the appropriate time for symptom expression. European larch canker (ELC) is under quarantine regulation in the Maritime Provinces. ELC surveys were conducted in New Brunswick (NB), Nova Scotia (NS), Prince Edward Island (PEI), Newfoundland (NF) and Labrador. In 2000, surveys were concentrated along the boundary of the known distribution and in areas outside of the quarantine regulated areas, which comprise the southern half of NB (approximately), mainland NS and part of Prince County, PEI. An extensive survey was conducted to ensure that ELC does not occur in either Newfoundland or Labrador.

RESULTS AND COMMENTS: In Canada, European larch canker is found only in the Maritime Provinces with a known distribution that includes portions of NB, NS and PEI. A map of the plant quarantine regulated area for European larch canker is available online at the Canadian Food Inspection Agency (CFIA) website (http://www.cfia-acia.agr.ca/english/ppc/science/pps/1999maps/lwcan99.jpg). The results of earlier surveys in Atlantic Canada have been reported previously (Hurley et al, 2000).

In 2000, a total of 151 locations were surveyed in the Atlantic Provinces. Locations surveyed in NB, NS and PEI numbered 15, 45 and 32, respectively. All were negative, except for one new location just outside the previously known distribution in central NB (Figure 1). This is just inside the regulated area as defined by the CFIA.

In Newfoundland and Labrador, 59 locations were surveyed for ELC. Forty six locations were surveyed on the Island of Newfoundland and 13 in eastern Labrador. No ELC was found in Newfoundland or Labrador during this survey. An ELC distribution map for the Maritime Provinces is included as Figure 1.

ACKNOWLEDGEMENTS: The authors gratefully acknowledge the technical field assistance of Art Doane, Dave O'Brien and Tom Walsh.

CROP: Lodgepole pine

LOCATION: British Columbia, Northern Interior-Coastal Transition Forests

NAME AND AGENCY:
A.J. Woods
Regional Forest Pathologist, Prince Rupert Forest Region, BC Ministry of Forests, Bag 5000, Smithers BC, V0J 2N0
Tel: (250) 847-7478

TITLE: FOLIAR DISEASE ASSESSMENT IN YOUNG (1-20 YEAR OLD) LODGEPOLE PINE STANDS IN NORTH-WESTERN BRITISH COLUMBIA

METHODS: Dothistroma needle cast caused by *Mycosphaerella pini*, a foliar disease of lodgepole pine (*Pinus contorta*), has become prevalent throughout the north-west interior of BC in the past few years.

This survey focused on determining the incidence and severity of this foliar disease throughout juvenile lodgepole pine stands of the Kispiox Timber Harvesting Landbase (THLB) (Figure 1).

Figure 1. Location of the Kispiox Timber Supply Area, an administrative boundary that encompasses the THLB study area.

The Timber Harvesting Landbase is the area of Crown forest land that is accessible to logging activities. The total area of lodgepole pine leading stands in the Kispiox THLB is approximately 11,000 ha. A list of all stands aged 1-20 years with > 50% of their stocking comprised of lodgepole pine was compiled from the BC Ministry of Forests database. A random number was assigned to each of these candidate stands. The random numbers were then sorted and the first 100 stands were selected for surveys. The total area of surveyed stands was 1,196 ha or approximately 10% of the total population of pine leading stands.

Each selected stand was then surveyed with 2-m wide, 100 -m long transects up to a survey intensity of 0.5 % of the gross plantation area. The location of the transects was established on 1:10,000 scale maps prior to the field survey. All trees > 1.5m height within the transect were assessed for dothistroma needle cast. The year of first attack and an estimate of the percentage of the crown affected was made for all trees infected with foliar disease. The incidence and severity of foliar disease was determined for each plantation (e.g. 10% of lodgepole pine trees are more than 50% defoliated due to dothistroma foliar disease).

RESULTS AND COMMENTS: Dothistroma needle cast was present in 76% of stands in the study area. The growing season of 1998 was the first in which the majority of the lodgepole pine trees in the Kispiox were infected. Trees with the greatest amount of foliar disease-induced needle loss, however, had their first infections in the 1997 growing season or earlier. The severity of foliar disease depends on both the incidence of diseased trees and the degree of infestation on those trees. Trees with less than 20% of their foliage affected likely do not suffer measurable growth losses. Trees with more than 20% probably begin to suffer some growth losses. It is clear from some of the stands that were included in this survey and others I have seen, that once a tree has more than 80% of its foliage affected, significant growth losses occur.

There was a considerable range in foliar disease severity throughout lodgepole pine stands in the Kispiox. The percentage of live crown affected by foliar disease ranged from < 5 % to > 85 %. The percentage of trees affected in any one stand ranged from 0 to 100%. I have reported the severity of foliar disease based on the percentage of stands that have foliar disease incidence from < 25% to > 75% of their trees suffering from < 20% to > 80% defoliation (Figure 2).

The majority of infested stands have less than 25% of the trees infected (Figure 2). The most serious concerns are those stands that have greater than 50% of the trees more than 50% defoliated. Only 2% of the stands have a foliar disease severity of that magnitude. The disease outbreak does not appear to be subsiding yet so it is quite possible that more of the stands will suffer greater foliage losses.

It is not clear what has led to the current outbreak of foliar disease in the study area. It is likely that the unusually mild winters and wet summers of the past three to five years have contributed, as the spores of the pathogen are spread by rain splash (Peterson, G. 1981). The mild winters have likely resulted in less of the infected needles being shed during the winter. The spores from the infected needles can then be spread further up into the crowns of affected trees. If the weather of the past 3-5 years is in part responsible and the projections of global warming materialise, then the prognosis for the health of the lodgepole pine plantations in the Kispiox is not good.

TITLE/TITRE: PATHOGEN BIODIVERSITY IN PINE TREE COLLECTIONS UNDER URBAN ECOLOGICAL CONDITIONS, QUEBEC

INTRODUCTION AND METHODS: Pine (*Pinus* L.) species are among the most popular coniferous trees planted in urban and suburban landscapes and collections. In practice, forestry focuses on *ex situ* methods for conservation of the genetic resources of particular trees, utilising botanical garden plantations. The Montreal Botanical Garden (MBG) arboretum contains a collection of about 60 pines (species, varieties and cultivars) from around the world. Fungal attacks on various parts of pine crowns can cause serious damage under favourable ecological conditions. In urban areas, some attacks could be favoured by atmospheric impurities which cause the trees to appear chlorotic and thinner than in the surrounding landscape.

To establish an efficient control strategy for pathogens, a particularly important goal was to assess the phytosanitary condition of pine crown components or ecological niches (Cone = C; Branches = B, Needle = N; Seed = S). From 1996 to 2000, a survey at pathogenic fungi on pine was carried out at the MBG in a collection of 48 pine trees originating from North America, Europe and Asia. Twenty-eight pine taxa (age of trees > 5 yrs) were selected on the basis of chlorotic and necrotic symptoms in the crown. On average, three specimens from each taxon were sampled. Each taxon was located in a separate tree grouping. The distance between the pine groups within the arboretum was approximately 20 m. All samples were insect-free and were selected randomly. Samplings and evaluations were conducted three times per year during the growing period. Diagnoses were accomplished by microscopic examination and culturing fungi onto various artificial media.

RESULTS AND COMMENTS: A total of 27 fungal taxa were isolated from diseased material in specific host/ecological niche combinations. Seven species were found on all the CBNS (Cone-Branch-Needle-Seed) niches and six in CBS. Colonization of the CNS niches was associated with four fungal species, CS and N with three, B with two, and CN and S with one species. The most frequently occurring fungal species were *Sphaeropsis sapinea* isolated from 12 hosts, *Herpotrichia juniperi* and *Choanatiara lunata* from eight, and *Truncatella hartigii* and *Strasseria geniculata* from seven hosts each (Table 1). Future investigations will require more attention to the characterization of different fungal strains in order to establish an adequate sanitary control strategy. Moreover, information on the incidence of pathogenic fungi in arboreta might allow the early recognition of potentially important diseases.

CROP: Whitebark pine

LOCATION: British Columbia

NAME AND AGENCY:
S. Zeglen
Vancouver Forest Region, British Columbia Ministry of Forests, Nanaimo, British Columbia

TITLE: WHITEBARK PINE AND WHITE PINE BLISTER RUST IN BRITISH COLUMBIA - 1999

INTRODUCTION: Whitebark pine (*Pinus albicaulis*) is found in subalpine forests throughout the province south of 56 N latitude. The future survival of whitebark pine is threatened by its susceptibility to white pine blister rust (WPBR), an exotic disease caused by the fungus *Cronartium ribicola*. This note highlights the annual progress of a province-wide survey of whitebark pine first reported in CPDS last year.

METHODS: High-elevation stands in the Cascade and Coastal Mountain Ranges having a leading or significant component of whitebark pine were identified using the provincial forest inventory database. Once a stand was located, the surveyor visually inspected for WPBR on the first 50 live and dead whitebark pine trees encountered during a strip transect reconnaissance.

RESULTS: Of the 7043 whitebark pine trees examined in 1999, 1219 (17.3%) were dead (Table 1). Mortality on 558 (45.8%) of these dead trees could be directly attributed to WPBR. Due to the difficulty of diagnosing some dead trees, this figure is conservative as dead trees without obvious stem cankers were classified as dead due to other factors. These other factors include mountain pine beetle (*Dendroctonus ponderosae*), abiotic factors, and unknown or unidentified causes.

Of the remaining 5824 live trees, 1857 (31.8%) were alive but infected with blister rust. Of these infected trees, 1190 (64.1%) have stem cankers and will likely die within a few years. The remaining infected trees displayed branch cankers that may develop into stem cankers over time. In addition, many trees suffered defects such as basal sweep, forks, crooks, and damage from feeding by squirrels.

COMMENTS: The survey should be completed over the rest of the province in the next year.
