10 Abstract.

The knowledge of the effects of climate change on agro-ecosystems is fundamental to identify local actions aimed to maintain productivity and reduce environmental issues. This study investigates the effects of climate perturbation on the European crop and grassland production systems, combining the finding from two biogeochemical models. Accurate and high-resolution management and pedoclimatic data ~~has been were~~ employed. Results ~~has have~~ been verified for the period 1978-2004 (historical period) and projected until 2099 with two divergent intensities IPCC's climate projections, RCP4.5 and RCP8.5. We provided a detailed overview on productivity and the impacts on management (sowing dates, water demand, nitrogen use efficiency). Biogenic ~~GHG budgets~~ greenhouse gas balance (N₂O, CH₄, CO₂) were calculated, including an assessment of their sensitivity to the leading drivers, and ~~the compilation of~~ a net carbon budget ~~over on~~ production systems- was compiled. Results confirmed that a significant reduction of productivity is expected during the period 2050-2099, caused by the shortening of the length of the plant growing cycle associated to the rising temperatures. This effect was more pronounced for the more pessimistic climate scenario (-13 % for croplands and -7.7 % for grasslands) and for Mediterranean regions, confirming a regionally distributed impact of climate change in Europe. Non-CO₂ ~~GHG~~ greenhouse gas emissions were triggered by rising air temperatures and increased exponentially over the century, ~~being often higher than exceeding~~ the CO₂ accumulation of the explored agro-ecosystems, which acted as potential C sinks. Emission factor for N₂O was 1.82 ± 0.07 % during the historical period, rising up to 2.05 ± 0.11 % for both climate projections. The biomass removal (crop yield, residues exports, mowing and animal intake) converted croplands and grasslands into net C sources (236 ± 107 Tg CO₂eq y⁻¹ in the historical period), increasing of more than 20 % during the climate projections. Nonetheless, crop residues restitution ~~demonstrates to be~~ might represent a potential management strategy to overturn the C balance. Although with a marked latitudinal gradient, water demand will double over the next few decades in the European croplands, whereas the benefit in terms of yield will not contribute substantially to balance the C losses due to climate perturbation.

1 Introduction

Agriculture is facing a major challenge to meet growing food demand while limiting soil degradation, air and water pollution, and adapting to climate change impacts (Chaudhary et al., 2018; Olesen, 2017). Agricultural sector is the main source of non-CO₂ anthropogenic greenhouse gases (GHG) and is responsible for 78.6 % of nitrous oxide (N₂O) and 39.1 % of methane (CH₄) emissions worldwide (IPCC, 2018). Agricultural practice, which directly affect soil, plant and atmosphere, represent a strategic lever to counteract climate change by mitigating GHG emission and fostering soil C storage (Chabbi et al., 2017, Smith et al., 2008) achieving long-term (*i.e.* 2100) climate objectives (Fuss et al., 2016; Minasny et al., 2017; Smith et al., 2013).

Evaluating the impacts of climate on agricultural productions at local, regional and global scales is still a challenge nowadays (Fitton et al., 2019; Olesen and Bindi, 2002). The main source of uncertainty come from the representation of agroecosystems in models' framework, or from the approaches used to upscale data network and local experiments to regional scales (Ewert et al., 2011; Hansen and Jones, 2000; Tubiello et al., 2007). Notwithstanding that, is commonly recognised that a decrease in crop yields is expected towards the mid and the end of the century, with reductions extending to more than 10 % in some region of the world (Challinor et al., 2014). Decline in productivity is likely to be combined with an increase of the interannual yield variability due to climate extremes (Dono et al., 2016) and with a strong latitudinal gradient (Rosenzweig et al., 2013). In the northern hemisphere, which will benefit from the lengthening of the growing season, milder temperatures and wet conditions in the next decades, crop and grassland productions are expected to rise (Yang et al., 2015). Conversely, lower latitudes are going to face a rise of drought frequencies with a decline of winter rainfall, accompanied by a potential decline in productivity (Stagge et al., 2017). This geographical gap/divide would lead to ~~an~~-intensification of farming systems in northern regions, as ~~north~~northern Europe, to ~~an~~-extensification in the southern regions, such as the Mediterranean basin (Olesen and Bindi, 2012).

In line with the commitment to the Paris Agreement and the European Green Deal, EU set the objective to cut net GHG emissions by at least 55 % by 2030, compared to 1990 levels. In addition, EU aims to become climate neutral by 2050 (EC, 2020). ~~This~~These ambitious ~~target-contrast~~targets contrast with the agricultural ~~emission~~emissions which stagnated or even increased in the past few years (EEA, 2020). Reducing emission in agriculture imply the use of management options in crop and grassland systems aimed to increase the efficiency of fertilisers and feeding strategies, manage crop residues, tillage operations, irrigation and drainage, and increasing cropping diversification (Aguilera et al., 2013; Conant et al., 2017; Cowan et al, 2016; De Antoni Migliorati et al., 2015; Li et al., 2016; Smith et al., 2008; Smith, 2016, Voglmeier et al., 2019). While there is a consistent amount of experimental data regarding the effects of management options, a robust quantification of the effects of climate change on the actual crop and grassland production systems at regional scale are still scarce. Concurrently, the need to develop and implement higher tier methodologies to be applied at fine spatial scales is growing nowadays (Smith, 2012).

Dynamic simulation models are suitable tools to evaluate the multifaceted effects of climate change across agricultural production systems as croplands and grasslands (Brilli et al., 2017; Ehrhardt et al., 2018; Sándor et al., 2018). Models are able to isolate the contribution of single or combined factors, trace the evolution of the system components and observe the aptitude of the agricultural strategies to mitigation impacts. More recently, process-based models conceived for site scale representation were applied at the regional scales to *e.g.* calculate national GHG inventories (Smith, 2013) or build statistical models (Del Grosso et al., 2009; Haas et al., 2013). Major challenges to perform spatial assessment are represented by the availability of input data (Lugato et al., 2014; [Lugato et al., 2017](#)), the representativeness of the model to change of spatial scale (Hoffmann et al., 2016) and bias introduced in the aggregation or disaggregation of input data in representative homogeneous spatial areas (Constantin et al., 2019); [Hansen and Jones, 2000](#)). Furthermore, simulating agricultural productions with climatic projections, introduce a further degree of uncertainty which can be reduced with a sound assessment over historical data (Rosenzweig et al., 2013); [as proposed in this study](#).

This research aims to investigate, by means of [process-based simulation modelling models](#), the contribution and the impacts of climate change in the European [cropland crop](#) and grassland production systems towards the year 2100. The analysis focuses on plant productivity and biogenic GHG (N₂O, CH₄, CO₂) balance, outlining a detailed carbon budget for current agro-ecosystems and with two climate scenarios, an intermediate and a pessimistic one. [This Through high spatially resolution and detailed management representation, this](#) study provides [near and long term](#) projections of key agro-~~ecosystem~~[ecosystem](#) variables [in the near and long term](#) to support and help identify possible actions to maintain productivity and reduce environmental impacts.

2 Material and Methods:

The study was realised by using two agro-ecosystem models, CERES-EGC (Gabrielle et al., 2005) for cropping systems and PaSim (Riedo et al., 1998) for grassland-livestock systems. Models were run on a spatial resolution of 0.25°, which is equivalent to an aggregation of the output to a squared cell of 27.78 km side. Each cell has its characteristic soil properties, agricultural management and daily climatic data. The 0.25° grid was identified to attain an adequate representativeness of the spatial variability of the inputs, a representativeness of the local effects at European scale, and limit computational burdens (Hoffmann et al., 2016; Constantin et al, 2019). Two distinct periods of temporal aggregation have been considered. The “historical period”, based on meteorological records, soil and management measured data, outlines the effects of the current management on the agro-ecosystem, and is useful for testing the reliability of both models. The “climate scenarios”, based on the same as the historical management practices, trace the near- and the long-term impacts of climate change on the agro-ecosystems under study. These two different aggregation periods are compared between them to highlight the effects of climate change ~~scenarios~~ on the [studied](#) systems ~~under study~~. [The projection in the long. Long-term projections](#) are [mainly](#) provided to [evaluate assess](#) the impacts of ~~the~~ current management [for variable as on](#) soil organic carbon and the ~~related~~ GHG emissions.

2.1 Models

95 **CERES-EGC** (Crop-Environment REsources Synthesis – Environement et Grandes Cultures) model was used to simulate crop rotations in EUROPE. CERES-EGC is a process-based biogeochemical model in the soil-plant-atmosphere domain adapted from CERES (Jones and Kiniry, 1986). The model is designed to simulate C and N dynamics, the transfer of heat and the water exchanges from soil and plant with a daily time step, at the field scale. Inputs require meteorological and management data as forcing variables and soil and crop data as factors. Meteorological data are constituted by daily minimum and maximum
100 temperature, precipitation, global solar radiation and wind speed. Management includes tillage, irrigation, fertilisation, information of sowing and incorporation on crop residues. Soil is divided in sublayers with specific depth, and physical and chemical characteristics. Simulated crop species include maize (grain and fodder), soft wheat, durum wheat, rye, oat, barley, rapeseed, sorghum, sunflower, pea, sugar beet and soybean, with the possibility to select specific cultivars.

Soil C and N dynamics in the ploughed layer are simulated by means of the NCSOIL model (Molina et al., 1983; Nicolardot
105 et al., 1994), which is a nested module in CERES-EGC. NCSOIL compute nitrification, immobilisation and mineralisation of N, the decomposition of soil organic matter (SOM) after incorporation of crop residues and SOM formation. The module works with a series of specific pools, three pools for crop residues (easily fermentable carbohydrates, cellulose and lignin) and four endogenous pools (zymogenous and microbial biomass, active and passive humus), where CO₂ is released from the decomposition of each pool. N uptake by plants is calculated through a specific supply/demand scheme depending on mineral
110 nitrogen availability and root length density. CERES-EGC includes the model NOE (Hénault et al., 2005) for simulating N₂O emissions from denitrification and nitrification processes in the topsoil (0-20 cm depth). Denitrification and nitrification are computed from a soil-specific potential rate limited by unitless factors related to soil water content, soil temperature and substrate content (nitrates, NO₃, and ammonium, NH₄, for denitrification and nitrification, respectively). Plant growth is simulated according to the crop specific genetic potential and the photosynthetically active solar radiation absorbed by the
115 canopy. Potential dry matter production is constrained by air temperatures, soil water availability and N deficit.

PaSim (Pasture Simulation model) is a biogeochemical process-based model able to simulate C, N and water dynamics in the soil-plant-animal-atmosphere grassland system (Calanca et al., 2007). Five interacting sub-models of soil biology and physics, microclimate, vegetation and grazing herbivores constitute the model structure. The model runs on daily (or hourly) time step and inputs require soil property data, management and meteorological characteristics (global solar radiation, minimum and
120 maximum air temperature, relative humidity, wind speed, precipitation and atmospheric CO₂ concentration). The soil is described in six sublayers allowing to parametrise different soil depths with site-specific soil physical and chemical characteristics. Management includes grazing, mowing, N fertilisation. Grazing is considered as a dairy or suckling system managed by grazing periods with specific stocking density and live weight. Indoor periods are not simulated. Vegetation cover is considered as a homogeneous cover with a fixed legume fraction. The vegetation cover comprises root system and three
125 shoot compartments (laminae, sheaths and stems, ears) divided into age classes. Soil C dynamics (based on CENTURY model; Parton et al., 1994) are computed in five pools, a structural and a metabolic pool for fresh organic carbon (plant residues), and

an active, a slow and a passive pool for the microbial processed organic carbon. Photosynthetic C is allocated in plant (root and shoot) and can be lost as CO₂ by ecosystem respiration and as CH₄ through enteric fermentation.

130 Soil N inputs are represented by atmospheric N deposition, symbiotic N₂ fixation, mineral or organic fertilisation, animal
faeces and urine. These inputs, together with the nitrogen mineralised from the organic carbon pools, constitute the mineral N
pool. N availability for plants is reduced by losses via processes of immobilization, NO₃ leaching, NH₃ volatilization,
nitrification and denitrification processes. N₂O emission from nitrification and denitrification depends on substrate availability
(NO₃ or NH₄). These emissions are modulated by factors controlling the effects of soil temperature and water content.
135 Furthermore, the release of N₂O produced into the soil toward the atmosphere is calculated with a resistance model in the
rooting zone and plant canopy (Schmid et al., 2001).

CERES-EGC and PaSim were selected as the most suitable models for a spatialized assessment since they have been calibrated
and evaluated in different conditions worldwide (Brilli et al., 2017; Ehrhardt et al., 2018; Sándor et al., 2018) and European
conditions in Europe, *i.e.* France, Denmark, Germany, Italy, Sweden, UK for CERES-EGC (Rolland et al., 2008; Lehuger et
al., 2009; Wattenbach et al., 2010, Drouet et al., 2011; Lehuger et al., 2011; Goglio et al., 2013; Ferrara et al. 2021; Haas et
140 al., 2021) and France, Germany, Hungary, Ireland, Italy, Portugal, Spain, The Netherlands, UK for PaSim (Lawton et al.,
2006 ; Calanca et al., 2007; Gottschalk et al., 2007; Vuichard et al. 2007; Ma et al., 2015; Sándor et al., 2016). These models
can globally simulate a number of crops and rotations, mown or grazed grasslands, and the effects of management practices
on plant-soil- atmosphere interactions. Besides, they are able to simulate GHG emissions and the carbon budget at the field
scale through the C assimilated from the photosynthesis, C emitted into the atmosphere from autotrophic and heterotrophic
145 respirations, C recycled into the system (dung, plant residues) or introduced from external sources (fertilisers, soil improvers),
and the C exported from the system by production activity. CO₂ fertilisation was not simulated for croplands (see S.4 in the
supplementary material). Also, the two models used in this study do not represent potential impacts of air pollution, pest and
disease effects on plant production.

2.2 Input data set

150 2.2.1 Climate data

Historical and climate projections data were used in this study to analyse the likely effect on GHG, productions and soil C
stocks in European production systems. We selected two of the four climate scenarios, or “Representative Concentration
Pathways” (RCPs) adopted by the IPCC for the fifth Assessment Report (AR5) (IPCC, 2013), an intermediate scenario,
RCP4.5, and a pessimistic one, RCP8.5.

155 Climate data were provided by the Earth System model HadGEM2-ES (Collins et al., 2011) and were downscaled to a
horizontal grid with 0.5° side resolution in the framework of the Inter-Sectoral Impact Model Intercomparison Project (ISI-
MIP; Warszawski et al., 2014). Since the spatial resolution of the climatic data is larger than the size selected for the simulation
units (0.25°), 4 adjacent simulation units were subjected to the same meteorological data. Data were not downscaled to

maintain data accuracy as much as possible. Data has been shaped for the European surface (29.0° to 71.5° Latitude and -24.0° to 45.5° Longitude). HadGEM2-ES model provided daily values of minimum and maximum air temperature, total precipitation, air specific humidity, shortwave radiation and near surface wind speed, for the period 1951-2099. Based on these data, input variables for each model were assigned. The simulation protocol consists of a historical dataset, from 1978 to 2004, constituted in accordance with HadGEM2-ES model using the historical record of climate forcing factors (Jones et al., 2011), and two climate projections RCP4.5 and RCP8.5, from 2005 to 2099.

165 2.2.2 Soil data

Soil data were obtained from the European Soil Database (ESDB; Hiederer, 2013). The ESDB is composed by 1 km × 1 km raster files containing topsoil (0 to 30 cm) and subsoil (30 cm to maximum soil depth) data of clay, silt, sand, gravel, and soil organic carbon (SOC) content, bulk density and maximum root depth. Soil pH for the topsoil was derived at the same spatial detail from the ESDB dataset provided by Reuter et al. (2008). To define soil characteristics for each spatial simulation unit of 0.25° side, the most recurrent soil was selected, accordingly with their characteristics. Organic soils with SOC content over 30 kg C m⁻² were excluded (3.4 % of the total simulation units), as well as forest soil. Model-specific soil input parameters were calculated on the base of the elementary characteristics (see supplementary material S.1 for details). For both models, a fixed number of six soil layers was established with a thickness defined as a function of the maximum soil depth. Organic soils with SOC content over 30 % were excluded from the simulations (3.4 % of the total simulation units).

175 2.2.3 Crop data

Crop species and N fertilisation amount for European Union on the 1 km × 1 km grid were provided in the framework of the GHG-Europe project (EU FP7; Wattenbach et al., 2015) at a spatial resolution of 1 km × 1 km grid. These data are based on the statistical crop distribution of Eurostat database (European Statistical Office, 2019a) and FAO databases at regional scale (NUTS2 regions or NUTS0), and on the simulation of the CAPRI model (Common Agricultural Policy Regionalized Impact; Britz and Witzke, 2008; see Leip et al., 2008). Nitrogen model. The amount of nitrogen fertilisation amount and was provided per crop species at the above-mentioned resolution, while the repartition between mineral and organic nitrogen forms were also provided at NUTS2 scale.

Crop successions were available for the period 1976 to 2010. We only considered the crop successions from the time interval 1978 to 2010 since the crop species used in the two discarded years (1976-1977) were never reused over the time series, and represented less than 1 % of the crop successions (*i.e.*, summer cereal mixes without triticale, other cereals including triticale, winter barley, flax, hemp and set aside). The two most frequent crop successions were selected as a reference for each simulation unit. In fact, they cover on average up to 93 % of the total agricultural area of the simulation units (median over all the simulation units with two rotations equal to 100 %). Based on this aggregation, the simulated crops were: summer/spring soft wheat, winter soft wheat, durum wheat, summer/spring barley, grain maize, fodder maize, rapeseed, sunflower, pulses, oats and sugar beet. Crop rotations included also winter rye, rice and potato, which were not explicitly parameterised in

CERES-EGC model, and were respectively substituted with specific varieties of soft wheat for rye and rice (the latter in the end was not represented in the rotations) and with sugar beet for potato. To define the crop species in the period 1951 to 2099, primary and secondary successions were replicated for all the years preceding and succeeding the time interval of available data (1978-2010). Furthermore, most adapted and calibrated crop varieties were designated in function of the latitude, based
195 on previous work and modellers' experience by using the CERES-EGC crop database.

Sowing dates were defined for each crop species, for each simulation unit and per year, based on a crop-specific time window, as well as a minimum and a maximum threshold temperature. Crop-specific windows were extracted from the assessments of USDA (1994) and Sacks (2010), selecting the minimum and the maximum typical sowing span over Europe, whereas threshold temperatures were extracted from Steduto et al. (2012). Given their width, time windows were not changed over time. The
200 sowing date was defined as the earliest within the time window, when minimum and maximum temperatures were respectively higher and lower than the thresholds. An additional constraint (no precipitation for three days in a row) was applied to consider farmers practice concerning access to the field. If a suitable sowing date was not identified, a fixed date was imposed in the middle of the time window. Residues were managed based on crop specie, exporting half (50%) of the aboveground cereal straws, 80% of the fodder maize and removing 20% from the residues of all the other crop types (harvesting losses), including
205 grain maize (Scarlat et al., 2019). Typical sowing crop densities were imposed based on Steduto et al. (2012). Fertilisation amounts ($\text{kg N ha}^{-1} \text{ year}^{-1}$) were defined as the average amounts designed for each of the crops in the most frequent succession in the simulation unit. Splitting and fertilisation dates were established based on crop type and the sowing date, total nitrogen amount and mineral to organic repartition (see supplementary material S.2 for details).

Irrigation was automatically supplied to the simulation unit which are defined as irrigable in the EU for the year 2016;
210 "irrigable" is considered as the area equipped for irrigation greater than 5 % of the utilised agricultural area (Eurostat 2019b). This share was 36 % of the EU and is mainly in the Mediterranean area, southern France and north-west of France, the Netherland and some regions in Denmark, Germany and the UK. The amount of water was distributed automatically at the rate of 10 mm d^{-1} when the soil available water content was below 90 %. This means that non-irrigated crops had access to irrigation water. Even if in the coming decades the global irrigated area is not expected to grow further due to water scarcity
215 and limited land (Turrall et al., 2011), to account for a possible increase of the irrigable share toward 2100, a management scenario to observe the maximum potential irrigation water demand for today's crops grown in Europe was simulated and discussed. This management is evaluated over the century by the two scenarios i_RCP4.5 and i_RCP8.5.

2.2.4 Grassland and livestock data

Grasslands data considered permanent grassland and rainfed temporary grassland. Nitrogen fertiliser application for European
220 grasslands in a 0.25° side resolution grid was estimated on the base of regional and national statistics (Eurostat) and CAPRI model (Leip et al., 2008). Data were generated combining fertilization managements and nitrogen doses, together with number of mowing events, animal loads, amount of mineral fertilizers and / or organics, and the fraction of leguminous. Mowing dates were defined from temperature using thermal sums ($500 \text{ }^\circ\text{C-days}$ from the first of January) on a base of $5 \text{ }^\circ\text{C}$. No cutting was

performed before such thermal sums was not obtained. Fertilisation events occurred three days after mowing. Grazing started
225 30 days after the first mowing event and ended either at the end of the year or at the first freezing period of five consecutive
days. Livestock were represented in the model only by cattle. Livestock densities (LSU ha⁻¹) were obtained from 0.05° side
regional statistics (Wint and Robinson, 2007) multiplying the total number of animals per surface unit to 0.8, 0.1, and 0.1 for
cattle, sheep and goats, respectively. Finally, LSU density distribution was aggregated to the 0.25° side grid. As for cutting
and fertilization, if no thermal sums were reached, then no events were performed. Biomass production is considered as the
230 sum of the grazer intake and the cut biomass. For each grid cell, livestock is only fed by grass (*i.e.* no external feed is
considered). If the amount of daily aboveground biomass is not sufficient to grazing animals, animals are moved from the
pasture. In this study we simulate livestock as they contribute to N cycling and since are an important source of nitrogen in
grassland, although we do not discuss here their productions.

2.2.5 Models spin-up and computation

235 CERES-EGC and PaSim were first initialised with soil C, along with the chemical and physical soil parameters, taken from
the ESDB for the year 2013. Then, for cropland, an equilibrium was set through a spin-up run using the weather period from
year 1951 to 1977 assuming that the cultivated area during this period was likely to have been continuously cultivated with
the same crop successions. Equilibrium was reached before 1971 for all the pixels with an estimation error lower than 0.1% of
the relative variation in the soil C balance in 5 years. For grasslands, we first let derive the simulation for each pixel from 1840
240 based on HadGEM2-ES weather data. Following, transformation rules were applied to move from past towards current
management practices, *i.e.* from 1901-1950, a low intensification management level with no mineral fertilization and cut at
900°C-days were applied. From 1951 to 2010, there was a gradual management intensification up to achieving the target levels
(linear increase of quantities, progressive earlier shift of cutting date). In this period, mineral nitrogen fertilization was applied,
starting with a low level in 1951. Finally, from 2010 to 2100, constant management according to the protocol come into effect.
245 A total of 86724 run divided in two land uses (8861 for arable, with two climate scenarios, two crop rotations and two irrigation
scenarios; 7918 unit for grasslands, with two climate scenarios) were simulated in a dedicated server.

2.3 Greenhouse gas exchange and balance

For assessing the net greenhouse gas exchange (NGHGE) of the investigated ecosystems, the contribution of the biogenic
GHG (CO₂, N₂O, CH₄) is combined and normalised to grams CO₂-equivalents by using the relative global warming potential
250 (γ_{gas}) at the 100-year time horizon (298 for N₂O, 25 for CH₄ and 1 for CO₂; IPCC, 2018), following the approach presented
by Soussana et al. (2007):

$$NGHGE = NEP + \gamma_{N_2O} F_{N_2O} + \gamma_{CH_4} F_{CH_4}$$

The net ecosystem production (NEP) is the amount of organic C available for net ecosystem C storage, export or loss in an
ecosystem, in terms of CO₂. NEP represents the difference between the gross primary production, or photosynthesis, and the

255 ecosystem respiration, which is the sum of the autotrophic and heterotrophic respirations (HR); ruminant respiration from grasslands ecosystems is not accounted in the HR term. Conventionally, a negative value of NEP stating an uptake of CO₂ by the system, whereas a positive value is a release in atmosphere.

The annual net greenhouse gas balance (NGB) is calculated on the base of Ammann et al. (2020) by including the export of C by harvested biomass (crop yield, mowing and animal intake), the export of crop residues and the import of C by manure
260 (organic fertilizers and the excreta from grazers):

$$NGB = NGHGE + F_{C-harvest} + F_{C-residues} - F_{C-manure}$$

As livestock were not grazing all year, their contribution to the carbon balance is represented by the intake of biomass, enteric fermentation (CH₄) and C in excreta. Carbon emissions from farm operations (*i.e.* tractor emissions), erosion and leaching processes, fire or off-farm emissions (*i.e.* fertiliser manufacture, barns) are not included in the C budget, as well the effects of
265 volatile organic compounds and CH₄ emissions from manure and from soil are considered as negligible. Moreover, the C exported from animal production (body mass increase and milk production) is neglected from NGB calculation (*e.g.* Chang et al., 2015).

3 Results:

3.1 Cropland and grassland productions

270 3.1.1 Model validation

Simulated crop yields during the historical period ranged between 1.4 and 44.8 t ha⁻¹ (as standard humidity) and were in good agreement with EU statistics reported in the Eurostat database (Eurostat, 2020) for the time span 1978-2004 (Fig. 1a; the time span considered represents the original crop rotation data and complies with the beginning of the climate scenarios). Root Mean Squared Error (RMSE) was equal to 2.24 t ha⁻¹, Mean Absolute Error (MAE) to 1.32 t ha⁻¹ and the modelling efficiency (Nash and Sutcliff, E) scored 0.96. Simulations with CERES-EGC overestimated the yields for grain maize, wheat, rye, oats,
275 soybean and sunflower, whereas potato, pulses, rapeseed, fodder maize, barley and sugar beet were slightly underestimated. The relative RMSE (RRMSE) for each crop, individually, ranged from 12.8 to 38.6 % (Table S3). Furthermore, reducing the simulation period to 1994-2004 to limit the effect of the crop annual genetic gain on measured data, the statistics above described were not modified (data not shown). The comparison between simulated and Eurostat statistics at country level
280 (NUTS0) for the 1978-2004 period given fitting results (RMSE = 5.58 t ha⁻¹; MAE = 3.18 t ha⁻¹; E=0.84) reported in Fig S2.

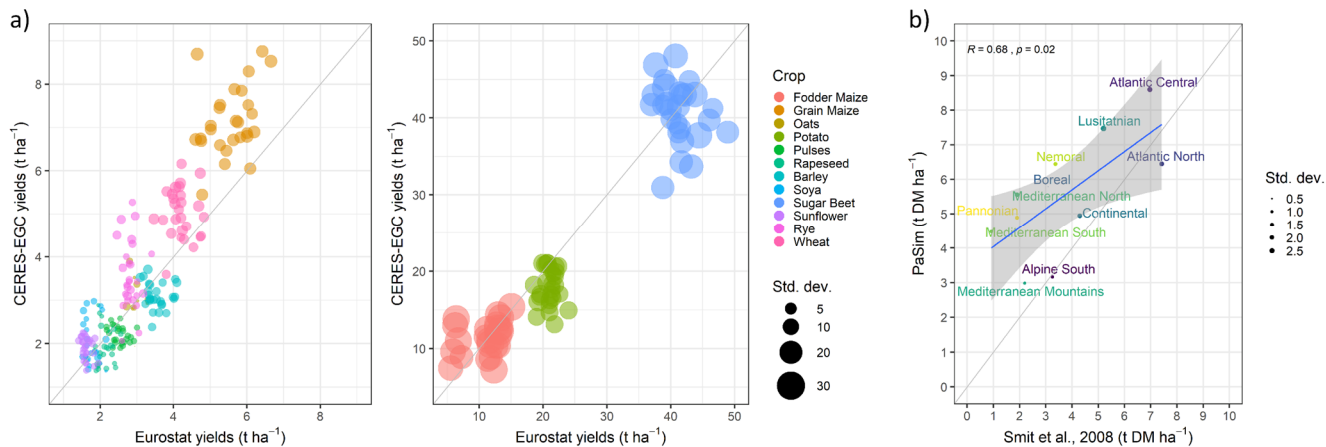

Figure 1: a) Simulated crop yields compared with Eurostat statistics in the period 1978-2004. Each point represents the yearly yield over EU for each crop; yields are reported as standard humidity. b) Grassland production compared to Smit et al. (2008) for the period 1995-2004. Point size represents the standard deviation (Std. dev.) of the simulated productions.

285

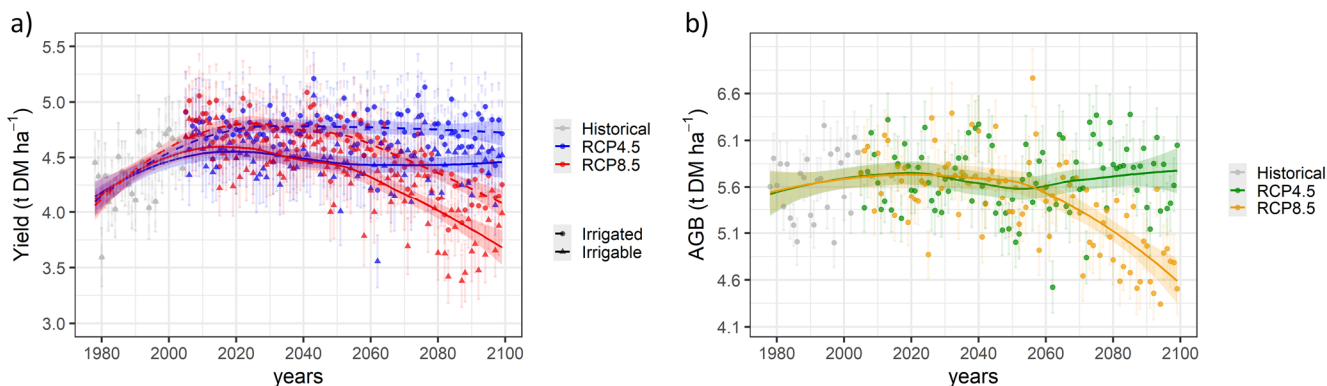

Representative data for grassland productions are still scarce at EU-level. Smit et al. (2008) computed the production of permanent grassland (pastures and meadows) across Europe based on national and international statistics for the period 1995-2004. The productivity simulated with PaSim (Fig. 1b) and aggregated to NUTS2 level (257 regions in this study) shown a significant positive spatial correlation ($r = 0.68$, $p < 0.05$) with the statistics reported by Smit et al. (2008), following the environmental stratification of Europe (Metzger et al., 2005). Compared to these statistics, PaSim scored a RMSE of 2.37 t DM ha⁻¹ y⁻¹, a MAE of 2.04 t DM ha⁻¹ y⁻¹ and a negative E (-0.34). Simulated productivity was generally overestimated in the Mediterranean area (+55 %; representing 16 % of the surface) and eastern Europe (+20 %; representing 25 % of the surface). The overestimation in these areas is verified also by other modelling interpretation (van Oijen et al., 2014, Chang et al., 2015; Chang et al., 2017; Blanke et al., 2018) and is due to the gap between potential (maximum) simulated productivity and real harvest data. A slight underestimation of the simulated productions was recorded for the Atlantic North zone (-15 %; representing 8 % of the surface). Finally, livestock density and distribution were in line with the Eurostat findings at country scale for the period 1995-2004, ranging from 0 to 1.35 LSU ha⁻¹ (mean: 0.34 LSU ha⁻¹). Livestock densities were higher in Belgium, the Netherlands, Denmark and Ireland, and in some regions of Germany, France, Italy and Spain, as also reported by Lesschen et al., (2011). Further details regarding grassland productivity are reported in the supplementary material S.3.

300 3.1.2 Effects of climate change scenarios on productive systems

Our results showed increasing cropland and grassland productions in Europe during the historical scenarios (Fig. 2). Productions were positively correlated with the increasing air temperatures over this period. Mann-Kendall test highlighted a

positive linear increase ($p < 0.01$) in the mean annual maximum air temperature ($0.05 \text{ }^\circ\text{C year}^{-1}$) and minimum air temperature ($0.04 \text{ }^\circ\text{C year}^{-1}$), as well as in solar radiation ($0.02 \text{ MJ m}^{-2} \text{ year}^{-1}$).

305 Crop production in Europe assumed a positive yearly increase during the historical period ($18.1 \text{ kg DM ha}^{-1} \text{ y}^{-1}$; Fig. 2a), which persisted until 2020, reaching 4.6 t DM ha^{-1} (average 2005-2020). Crop production raised in the first half of the century for both climatic scenarios ($+5 \%$ compared to the average of the historical period; Table 1), even if the rate of increase slow over time, especially from year 2020 to 2050. In the second part of the century, crop production remained stable for the scenario RCP4.5 ($+2 \%$ compared to the average of the historical period), while a reduction of -6% is forecasted for the RCP8.5 scenario; this decline reached -13% in the end of the century (period 2080-2099). The extension of irrigation to all European croplands foster crop productions to $+10 \%$ in the first half of the century, while in the second part of the century crop productions were sustained only for RCP4.5 and irrigation mitigates the projected decline for RCP8.5 ($+2 \%$ compared to historical period).

315

Figure 2: a) Crop yield trends in Europe from 1978 to 2099 with the two climatic scenarios RCP4.5 and RCP8.5, and two irrigation conditions following the irrigable agricultural area in Europe or extending the irrigation to all the arable lands (i_RCP4.5 and i_RCP8.5); all crops confounded. b) Grassland yield reported as the sum of biomass mowed and ruminant intake.

320

Crop production showed a clear trend over latitudes and over time. During the historical period, crops were more productive in low latitudes ($< 45^\circ$) than in mid latitudes ($45^\circ\text{-}55^\circ$; -25% compared to low latitudes, $p \gg 0.05$) and higher latitudes ($> 55^\circ$; -46% compared to low latitudes, $p \gg 0.05$). These gaps were reduced during the climate scenarios (Table S1). In low latitudes yields were comparable with the historical period in the first half of the century, undergoing to severe reductions towards the end of the century (-4% and -11% for RCP4.5 and RCP8.5, respectively). Moving to mid and to high latitudes crop productions increased in the first part of the century for both climatic scenarios (from $+5 \%$ to $+12 \%$). In the second part of the century, productivity was maintained only for mid latitudes in the RCP4.5 ($+3 \%$), whereas declined for the RCP8.5 scenario (-8%).

High latitudes were characterised by a further increase towards the end of the century (+14 % and +12 % for RCP4.5 and RCP8.5, respectively).

330 The yield of the two most cultivated crops in terms of area in Europe, grain maize and winter soft wheat, were not negatively affected by climate perturbations in first half of the century with the RCP4.5 scenario, while a slight increase is expected in the RCP8.5 for grain maize (+2 %; average 2030-2049) and a decrease for winter soft wheat (-4 %). Drastic reductions are projected for grain maize yield in the end of the century for both climate scenarios (-5 % in RCP4.5 and -19 % for the RCP8.5, average 2080-2099). Conversely, production is expected to increase for winter soft wheat for RCP4.5 (up to +8 %), and a decline (-1 %) for RCP8.5 (Fig. S3a,b). The adoption of irrigation for all European croplands increased the productivity of grain maize compared to the irrigable scenario (+8 % toward mid-century for both scenarios; +13 % and +16 % toward the end of the century for i_RCP4.5 and i_RCP8.5, respectively). On the other hand, small yield increases are expected with the irrigation scenario for winter soft wheat.

Fig. 3 reports the length of the growing season for grain maize and winter soft wheat, underlining a consistent reduction during both climatic scenarios. Crop growing cycle considers that sowing dates were modulated according to climatic conditions. Compared to the historical period, in the middle of the century there was an average reduction of the growing season of -8 days for grain maize (-12, -5 and +9 days for low, mid and high latitudes, respectively) and -20 days for winter soft wheat (-20, -19 and -6 days for low, mid and high latitudes, respectively). This trend remained constant for RCP4.5 scenario toward 2100, whereas worsened for RCP8.5, with averaged reductions of -27 and -36 days for grain maize and winter wheat, respectively. Severe reductions are expected at mid and low latitudes for grain maize (-34 and -24 days), and at mid and high latitudes for winter soft wheat (-49 and -38 days). The length of the growing cycle for all the crop, except for potato and sugar beet, was reduced of -12 days in the middle of the century and reached -19 days in the second part of the century (Fig. S4). Conversely, potato and sugar beet shown an extension of the length of the cropping cycle over time in all scenarios, especially during the end of the century.

350

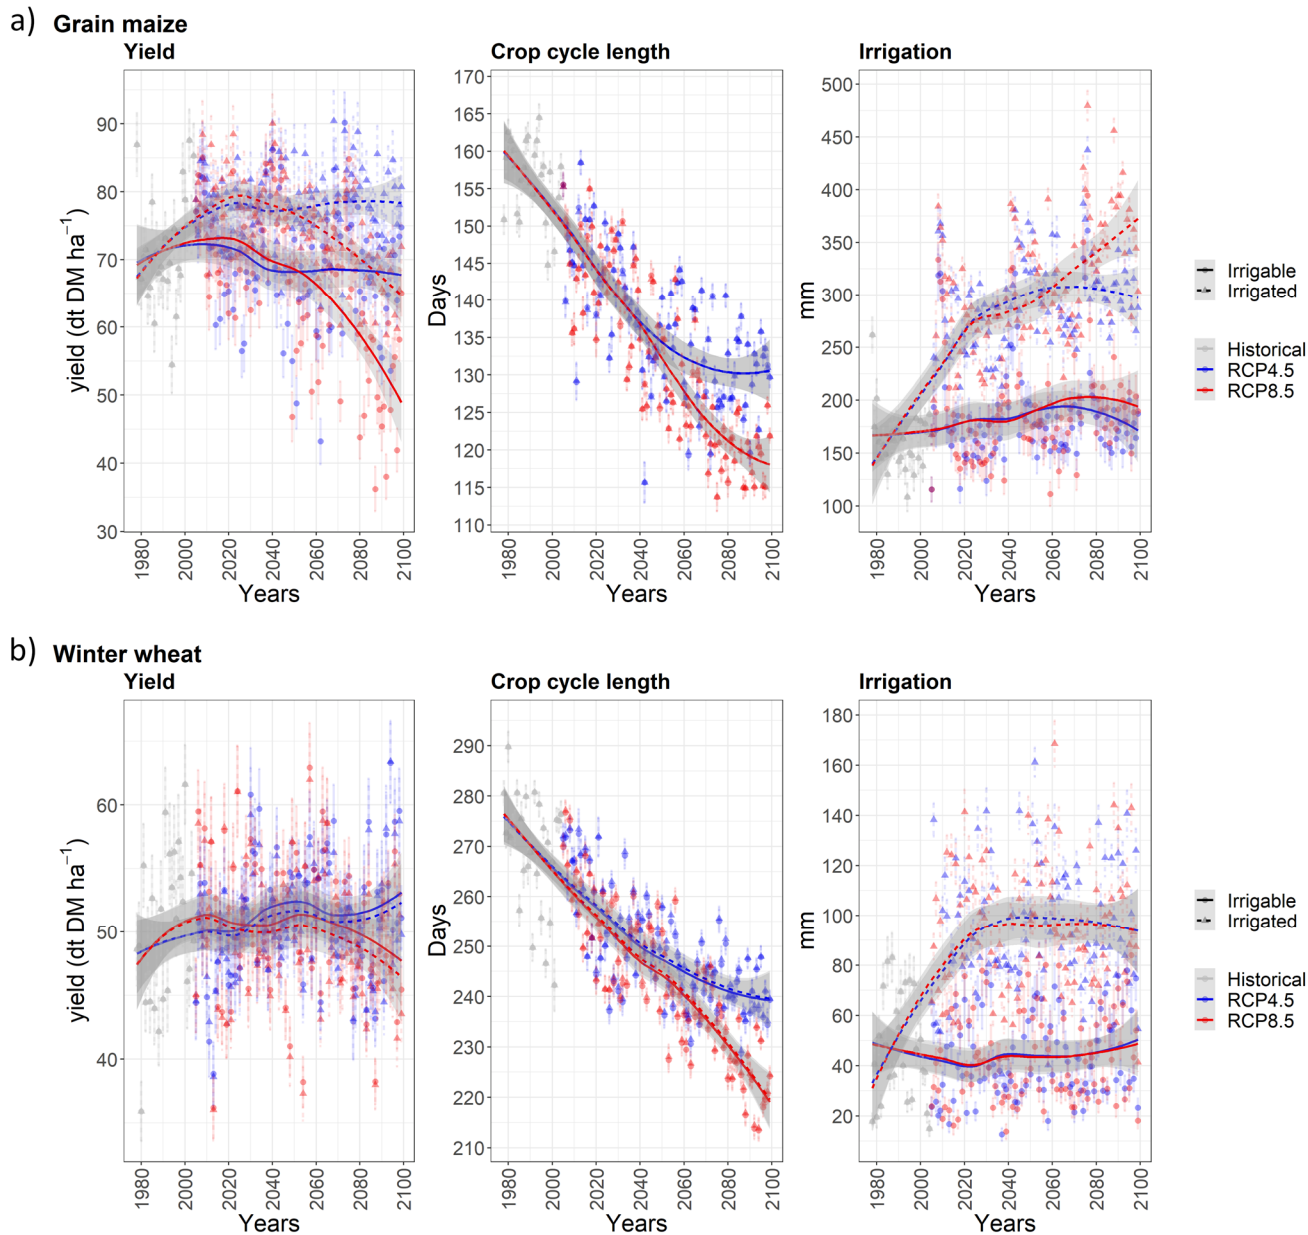

Figure 3: Yield, length of the cropping season and irrigation needed over the cropping cycle for fodder maize (a) and winter soft wheat (b) in the two climatic scenarios RCP4.5 and RCP8.5; figure reports results for the European the irrigable area and extension of the irrigation to all the European arable area (scenarios i_RCP4.5 and i_RCP8.5).

355

Considering the mild climate projections, positive yield increases from 4 to 20 % are expected for durum and soft wheat, soybean, rye and spring wheat for low latitudes and toward the end of the century. On the other hand, grain and fodder maize,

360 potato, barley, sugar beet, pulses and oats, are affected by substantial reductions (from -1 % to -44 %). The extension of
 irrigation is able to increase yields for the more water demanding crops (grain and fodder maize, sunflower, sugar beet and
 potato) with increases of more than +10 %. At mid latitudes strong reductions, in the range of -2 to -17 %, are expected for the
 large part of the main European crops (durum and soft wheat, potato, rapeseed, barley, soybean, spring soft wheat, sugar beet,
 and sunflower), whereas fodder maize and winter rye were projected to increase (+30 and +9 %, respectively). High latitudes
 displayed reductions in yields for pulses and barley (-22 % and -11, respectively), and an increase (+7 to over +100 %) for
 rapeseed, sugar beet, potato grain and fodder maize. The extension of irrigation to all European croplands will not make
 365 sensible improvement for mid and high latitudes yields for i_RCP4.5, while a substantial reduction is projected for all the
 crops in i_RCP8.5.

Table 1: Emissions of N₂O, CH₄, the net ecosystem production (NEP; for signs convention, negative values represent a stock of carbon), and productivity from grassland and croplands. Between brackets is standard deviation.

370 ^a Yield for croplands; the sum of harvested biomass and animal intake for grasslands.

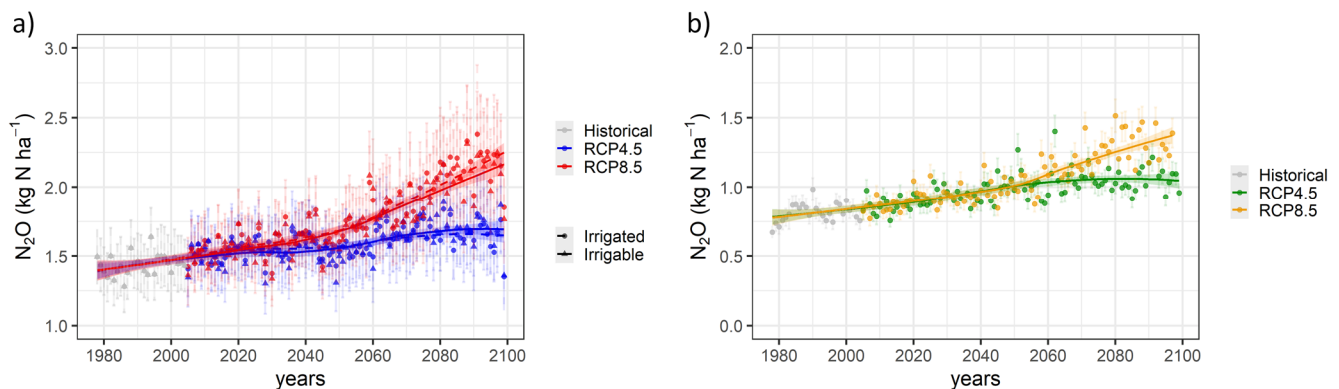

Irrigation was applied to 93 % of all the simulation units, doubling the volumes needed to fulfil the evapotranspiration deficit (160 mm y⁻¹ in the first half of the century) compared to the historical period (82 mm y⁻¹). Then, water volumes needed in the second half of the century are reduced for i_RCP4.5 (114 mm y⁻¹) and are slightly increased for i_RCP8.5 (176 mm y⁻¹).

375 Compared to the scenario with actual irrigable surface, these volumes increased by more than 2 and 5 times at mid and high latitudes and only by +30 % at low latitudes, indicating that the extension of irrigable areas became an essential to ensure adequate levels of crop production, especially in the Mediterranean regions.

Grassland productivity showed a trend over time similar to croplands (Fig. 2b; Table 1). Compared to the historical period, grassland productivity slightly increased until 2020 to decline toward the middle of the century, with an average production of 380 5.6 t DM ha⁻¹ (average 2030-2049). Biomass productivity is maintained during the progress of the RCP4.5 scenario, whereas an averaged reduction of about 0.45 t DM ha⁻¹ (-7.7 % compared to the historical period) is expected for the RCP8.5 scenario in the second part of the century. During the historical period, grassland productivity at low latitudes was about 30 % lower compared both to mid and high latitudes, with higher productions concentrated in the north-west Europe. A substantial increase of production was observed toward 2050 both for low latitudes (+9 % for RCP4.5 and +10 % RCP8.5) and high latitudes (+13 385 % and +14 % for RCP4.5 and RCP8.5, respectively; Fig. S3c and Table S1 in the supplementary material). Moving to the end of the century, grass production increased further compared to the historical period, especially for RCP4.5 (+16 % and +22 % for low and high latitudes, respectively), while a less marked increase is expected for RCP8.5 (+6 % and +13 % for low and high latitudes, respectively). At central EU latitudes, characterised by a higher livestock density than low and high latitudes (+42 % and +13 %, respectively), productivity was reduced of -6 % in RCP4.5 and -5 % in RCP8.5 in the middle of the century. 390 This reduction remains constant for the RCP4.5 scenario toward the end of the century and was more pronounced for RCP8.5 (-24 %).

3.2 GHG emissions

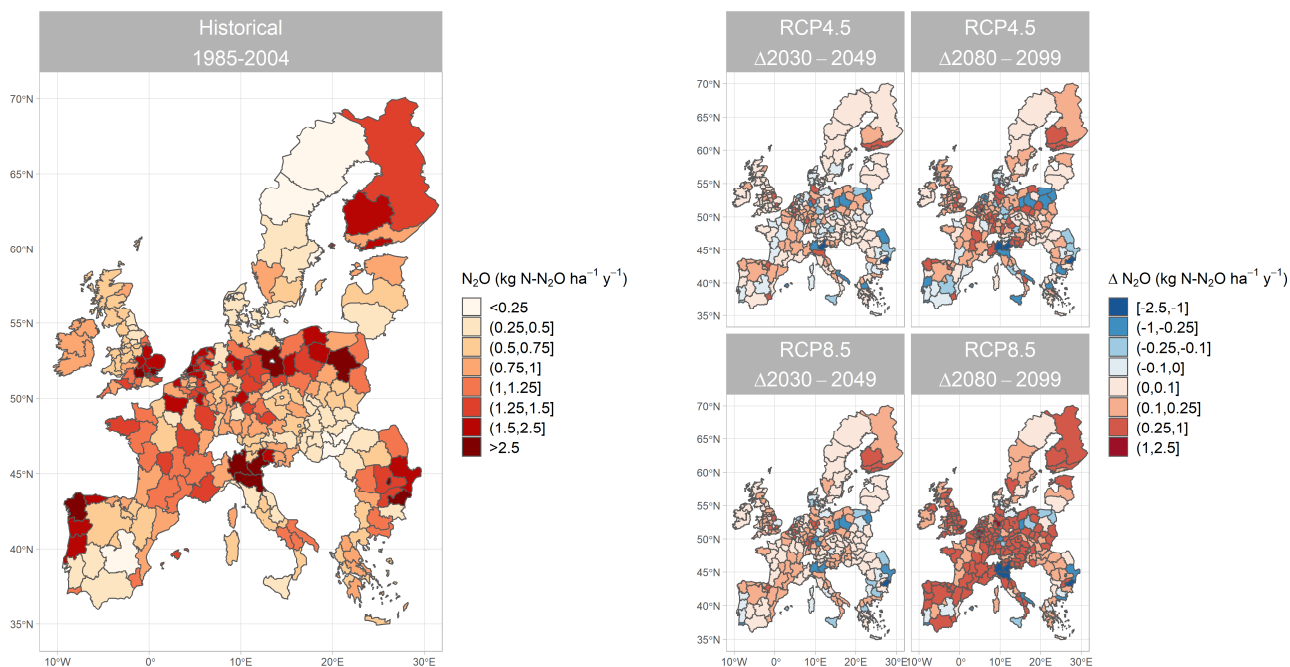

3.2.1 N₂O emissions

395 **Figure 4:** a) N₂O emissions (kg N ha⁻¹ y⁻¹) for croplands and b) grassland with two climate change scenarios (RCP4.5 and RCP8.5). N₂O emissions for croplands consider two irrigation conditions, following the irrigable agricultural area in Europe or extending the irrigation to all the arable lands (i_RCP4.5 and i_RCP8.5).

N₂O emissions increased sharply for croplands along the century for both climate scenarios (Fig. 4a). During the historical
400 period, a stable growth of the emission at the rate of 2.2 g N-N₂O ha⁻¹ y⁻¹ is observed, with a mean value of 1.44 kg N-N₂O ha⁻¹
y⁻¹ (Table 1). This rate decreased to 1.3 g N-N₂O ha⁻¹ y⁻¹ in the first half of the century for RCP4.5 scenario, while a rise of
2.9 g N-N₂O ha⁻¹ y⁻¹ is forecasted for the RCP8.5 scenario. In the second part of the century, the rate of emission was nearly
tripled for RCP4.5 compared to the emission in first half of the century. A strong increase of emissions is observed for RCP8.5,
405 with a rate of 10 g N-N₂O ha⁻¹ y⁻¹, reaching a mean of 2.09 kg N-N₂O ha⁻¹ (average 2080-2099). RCP4.5 scenario, instead,
reach a total of 1.69 kg N-N₂O ha⁻¹. The extension of irrigation to all European croplands amplified the emission rates in the
first half of the century for both i_RCP4.5 and i_RCP8.5, compared with the irrigable scenario (+3 % and +26 %, respectively).
Emission rates decreased in the second part of the century for i_RCP4.5 (-34 %), whereas grown up to +17 % for i_RCP8.5.
Furthermore, the interannual variance of N₂O emissions increased from the historical period to the first half of the century
(+15 % in both scenarios) and continued for the second part of the century (+41 % and +75 % for RCP4.5 and RCP8.5,
410 respectively). While, the extension of irrigation was able to reduce the interannual variance for both i_RCP4.5 and i_RCP8.5
scenarios (+17 % and +61 %).

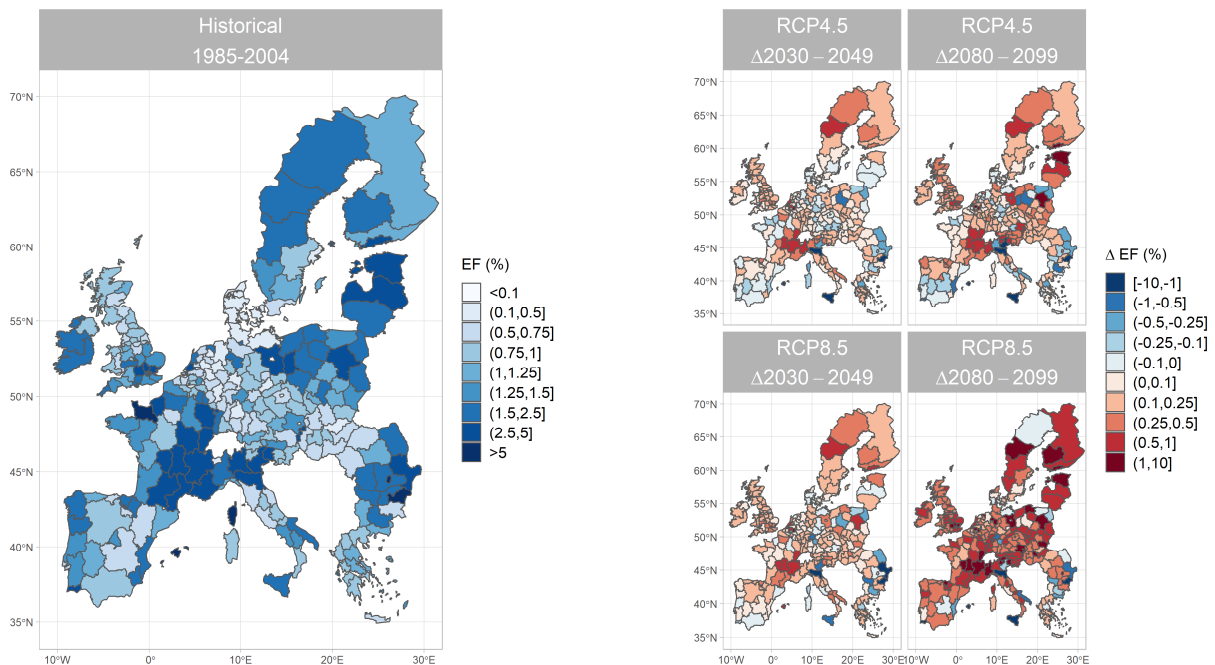

N₂O emissions from grasslands described a similar trend over the years as for croplands (Fig. 4b), characterised by lower rates.
During the historical period, the emission increased at a rate of 2.4 g N-N₂O ha⁻¹ y⁻¹, with a mean value of 0.81 kg N-N₂O ha⁻¹
y⁻¹ (Table 1). The rate raised to about 3.6 g N-N₂O ha⁻¹ y⁻¹ during the first half of the century, afterwards the two different
415 climate scenarios shown different trends. RCP4.5 was characterised by a significant reduction of the emission rate to 0.5 g N-
N₂O ha⁻¹ y⁻¹, while the rate tripled for RCP8.5, reaching 1.32 kg N-N₂O ha⁻¹ y⁻¹ in the end of the century (average 2080-2099).
A total emission of 1.05 kg N-N₂O ha⁻¹ is expected for RCP4.5.

420 **Figure 5:** N₂O emission for croplands and grasslands in European administrative borders (NUTS2). Emissions are reported for historical period (1985-2004), and difference “Δ” with mid (2030-2049) and the end of the century (2080-2099) for the two climatic scenarios RCP4.5 and RCP8.5. N₂O emissions are reported in cropland with irrigable scenario (see the text).

Total N₂O emissions from croplands and grasslands were reported to the surface allocated for arable crops and permanent grasslands for each simulation unit, by using the share of Corine Land Cover inventory of 2018 (Fig. 5). Emissions ranged between 0 and 2.5 kg N ha⁻¹ y⁻¹ and were concentrated in hotspots, such as northern Italy, north-east Germany and Poland, southern England, Bulgaria, eastern Romania, the Scandinavian peninsula, the north-western of Spain and Portugal. During the climatic projections is observed a general worsening of N₂O emissions towards the end of the century, reaching up and often over ±1 kg N ha⁻¹ y⁻¹, especially for the strongest climatic scenario. An average of 1.02 kg N-N₂O ha⁻¹ y⁻¹ (corresponding to 0.163 Mt N-N₂O y⁻¹) were emitted during the historical period. This amount raised 1.06 and 1.08 kg N-N₂O ha⁻¹ y⁻¹ (0.166 and 0.170 Mt N-N₂O y⁻¹) in the first half of the century for RCP4.5 and RCP8.5, respectively. In the second half of the century total N₂O emissions assumed a further increase to 1.11 and 1.13 kg N-N₂O ha⁻¹ y⁻¹ (0.169 and 0.174 Mt N-N₂O y⁻¹) for RCP4.5 and RCP8.5, respectively. Separate emissions of N₂O from croplands and grasslands are reported in Fig. S5a,b.

The N₂O emission factor (EF), intended as the ratio between the N emitted as N₂O from croplands and grasslands, and the N introduced into the system (not including the N added by animal excretion, crop residue, atmospheric deposition, soil mineralisation and fixation), assumed the same trend described for N₂O over time. During the historical period the averaged EF for croplands was 1.88 % ± 0.32 %, while the EF for grasslands was 1.99 % ± 0.16 %, see Fig. S6a,b.

440 **Figure 6.** N₂O emission factor (EF %) for croplands and grasslands in European administrative borders (NUTS2). EF is
 reported for the historical period (1985-2004), and the difference “Δ” with the middle (2030-2049) and the end of the century
 (2080-2099) for the two climatic scenarios RCP4.5 and RCP8.5. EF is calculated as ratio between the N emitted as N₂O from
 croplands (irrigable surfaces) and grasslands, and the N introduced into the system (not including the N added by animal
 excretion, crop residue, atmospheric deposition, soil mineralisation and fixation).

445

Combining cropland and grassland emissions over each simulation unit, the resulting EF was 1.82 ± 0.07 % during the
 historical period, and rose to 1.90 ± 0.09 % for RCP4.5 and 1.94 ± 0.09 % for RCP8.5 in the first half of the century. EF was
 2.02 ± 0.11 % and 2.05 ± 0.11 % for RCP4.5 and RCP8.5, respectively, in the second part of the century. The spatial distribution
 of EF values at NUTS2 scale, as reported in Fig. 6, varies from 0.1 % to over 5 % in the historical period, to assume variations
 450 between ± 1 % in RCP4.5, and up to ± 10 % in RCP8.5. The hotspots are the same described for the N₂O emissions. The specific
 EF for the simulated crops, calculated in the period from sowing (including pre-sowing management) to the sowing of the next
 crop in a succession (excluding pre-sowing management), ranged from 0.9 % to 3.4 % in the historical period, and is reported
 in Fig. 7. EFs toward mid- and the end of the century raised for all the crops, with a greater impact for the RCP8.5 scenario,
 except for winter soft wheat, which exhibited lower EFs values over the century, and soybeans which presented a low EF at
 455 the end of the century for RCP8.5 scenario compared to the less strong scenario. Fig. 7 reported the EF for N₂O also for
 grasslands, which assumed an increasing behaviour following the course of the century and the strength of climate scenarios.

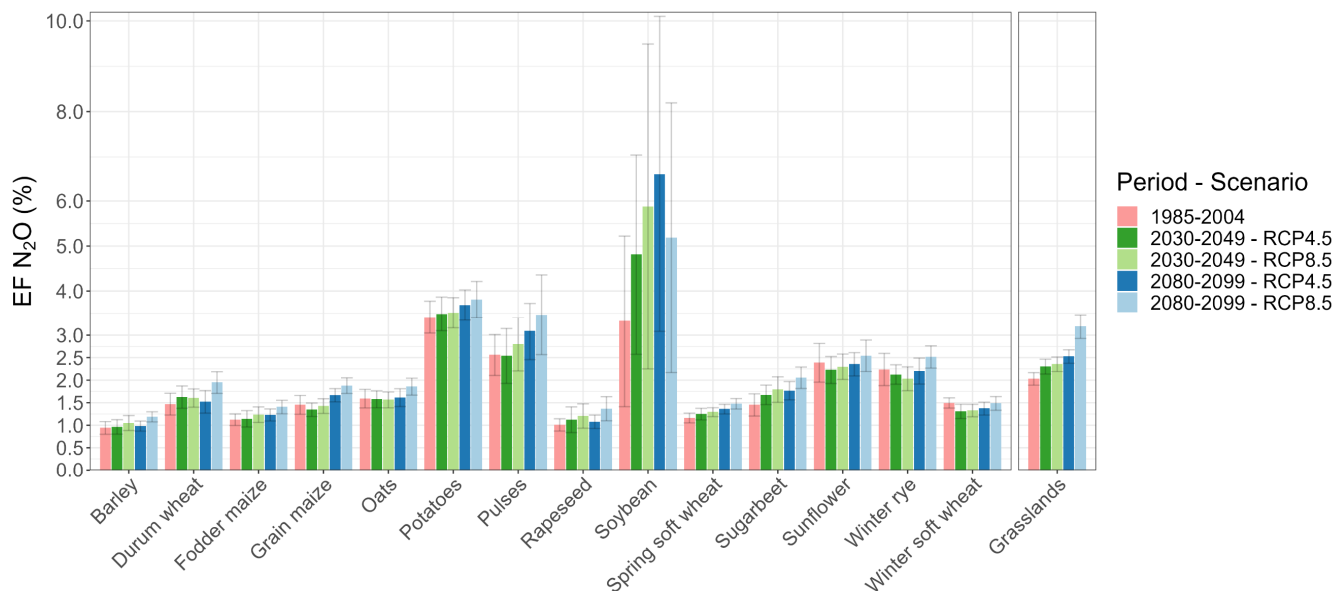

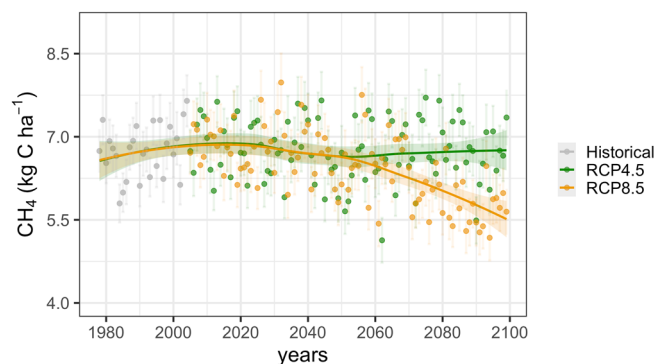

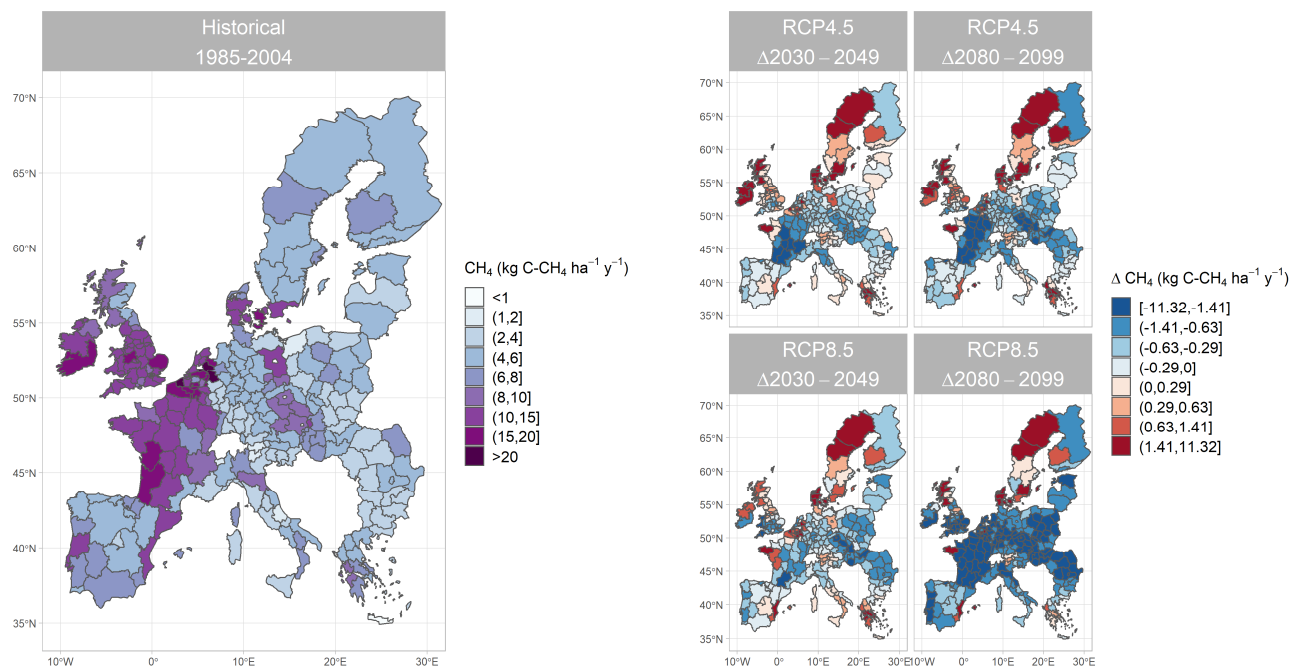

Figure 7: Emission factor (EF) for N₂O (%) for the different crops and grasslands for historical period (1985-2004), toward mid-century (2030-2049) and toward the end of the century (2080-2099), for the two climatic scenarios RCP4.5 and RCP8.5. EF is ratio between the N emitted as N₂O from crops and grasslands, and the N applied.

3.2.2 CH₄ emissions

The emissions of CH₄ from enteric fermentation are reported in Fig. 8. During the historical period, a mean emission of 6.71 kg C-CH₄ ha⁻¹ y⁻¹ was observed, with a rate of 15.6 g C-CH₄ ha⁻¹ y⁻¹ (Table 1). The emission rate halved in the first part of the century, to increase slightly in the second part of the century for RCP4.5 (4.3 g C-CH₄ ha⁻¹ y⁻¹) and strongly decrease for RCP8.5 scenario (-23.7 g C-CH₄ ha⁻¹ y⁻¹). Emissions toward the end of the year were 6.73 kg C-CH₄ ha⁻¹ y⁻¹ in RCP4.5 (average 2080-2099), and 5.74 kg C-CH₄ ha⁻¹ y⁻¹ for RCP8.5. The averaged CH₄ emissions per head ranged from 2.99 kg CH₄ head⁻¹ y⁻¹ in the historical period to reach 3.03 and 3.01 kg CH₄ head⁻¹ y⁻¹ in the first half of the century for RCP4.5 and RCP8.5, respectively. In the second half of the century a reduction to 2.98 and 2.73 kg CH₄ head⁻¹ y⁻¹ are expected for RCP4.5 and RCP8.5, respectively. The spatial distribution of CH₄ emissions at NUTS2 scale is reported in Fig. 9 and ranged from 0 to over 20 kg C-CH₄ ha⁻¹ y⁻¹ in the historical period and resulted concentrated in the north-west part of Europe. During the climate projections, methane emissions assumed variations in the range of ±12 kg C-CH₄ ha⁻¹ y⁻¹, with increases mostly concentrated in northern Europe.

475 **Figure 8:** CH₄ emissions (kg C-CH₄ ha⁻¹ y⁻¹) from enteric fermentation grasslands with two climate change scenarios (RCP4.5 and RCP8.5).

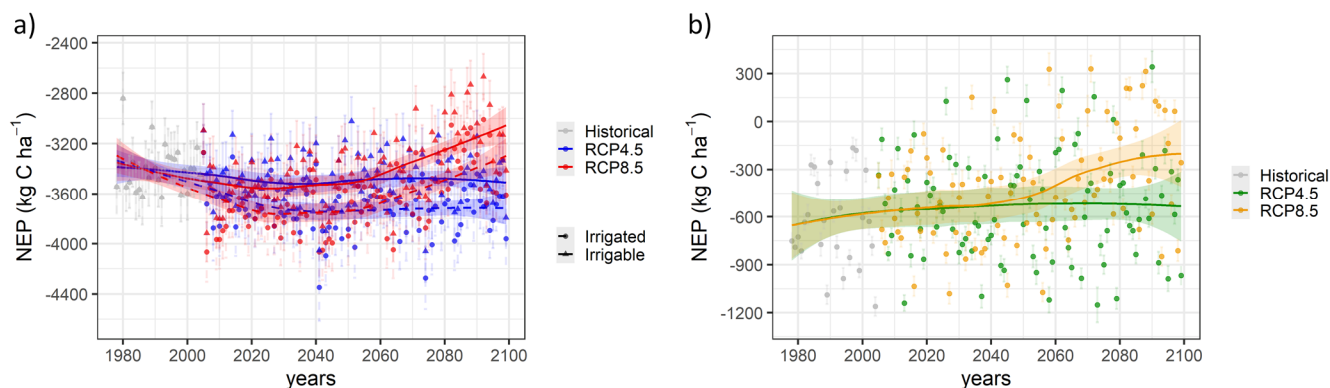

480 **Figure 9:** CH₄ emission for grasslands in European administrative borders (NUTS2). Emissions are reported for historical period (1985-2004), and difference “Δ” with mid (2030-2049) and the end of the century (2080-2099) for the two climatic scenarios, RCP4.5 and RCP8.5.

3.2.3 Carbon fluxes

Results are presented with sign convention indicating CO₂ accumulation as negative, and CO₂ losses as positive. Net Ecosystem Production (NEP) for European croplands showed a clear intensification of CO₂ accumulation until 2050. Rates

485 were contrasting for RCP4.5 and RCP8.5, -3.27 and $+1.44$ kg C-CO₂ ha⁻² y⁻¹, respectively (Fig. 10a; Table 1). In the second part of the century, a net divergence between the trends of the two climate scenarios is expected. CO₂ is continuously accumulated for RCP4.5 (-1.66 kg C-CO₂ ha⁻¹ y⁻¹), whereas a decrease is projected for RCP8.5 (9.84 kg C-CO₂ ha⁻¹ y⁻¹). Extending the irrigation area over all European croplands, which taken advantage of irrigation volumes according to crop needs and soil water status, produced a proportional increase of CO₂ accumulation in the climatic scenarios for both the first 490 half of the century (+6 %) and the second half (+7 %). NEP for croplands is expected to increase toward 2050 at low latitudes (+3 %) for both RCP4.5 and RCP8.5 (Fig. S7a; Table S1). This trend is inverted toward the end of the century for RCP4.5 scenario (-1 %), while turn to more severe for RCP8.5 (-8 %). In central European latitudes CO₂ is accumulated in the first part of the century for both climate scenarios (+9 %) and tended to be released in the end of the century for RCP8.5 (-3 %). Compared to central European latitudes, higher latitudes shown a trend to store more CO₂ for the RCP4.5 scenario respect to 495 the historical period (+5 % in the middle of the century and +9 % in the end of the century), whereas a tendency to release CO₂ is forecasted for the RCP8.5 scenario, especially toward the end of century (-5 %). The extension of irrigation to all European area showed a clear CO₂ loss towards the end of the century for low and mid latitudes, while a potential accumulation was observed at high latitudes.

500 **Figure 10:** Net ecosystem production (NEP; g C ha⁻¹) for croplands (a) and grasslands (b), with two climate change scenarios (RCP4.5 and RCP8.5), and two irrigation conditions following the irrigable agricultural area in Europe or extending the irrigation to all the arable lands (i_RCP4.5 and i_RCP8.5)

NEP in grasslands indicated a clear trend to CO₂ accumulation into the system during the historical period (Fig. 10b; Table 1), 505 with a rate of -0.77 kg C ha⁻¹ y⁻¹. Towards 2050 a slight imbalance and a tendency to release CO₂ is observed for both climate scenarios. Towards 2100, the amount of CO₂ potentially stored into the system is maintained for RCP4.5 with a loss of about 100 kg C-CO₂ ha⁻¹ y⁻¹ compared to the historical period (-622 kg C-CO₂ ha⁻¹ y⁻¹), while a clear tendency to CO₂ release was forecasted, on average, for the scenario without adaptation, RCP8.5. In the second half of the century RCP8.5 scenario projected a potential loss of 50 % of the CO₂ annually stored in the historical period. A potential release of CO₂ is also projected 510 for the RCP4.5 for low latitudes, both in the middle (-7 %) and towards the end of the century (-16 %), compared to the

historical period (Table S1). Higher decreases are forecasted for the RCP8.5 for the lower latitudes, -13 % and -37 % towards the first and the second half of the century, respectively. Conversely, for latitudes $> 55^\circ$ a potential storage of CO₂ is expected for RCP4.5 (+2 % and +3 % for the mid and the end of the century, compared to the historical period), whereas the scenario RCP8.5 gain more CO₂ in the middle of the century (+2 %) and turns to negative (-31 %) toward the end of the century. The intermediate latitudes, corresponding to the central Europe, displayed a strong susceptibility to CO₂ release in both climatic scenarios, ranging between -19 % and -31 % for RCP4.5 in the middle and at the end of the century, respectively, and turning to more negative and equal to -50 % and -100 % for the RCP8.5 scenario (Fig. S7b).

NEP of the European cropland and grasslands system, obtained reporting emissions the surface allocated for arable crops and permanent grasslands in each simulation unit, is reported in Fig. 11. During the historical period, NEP varied between -7500 and +200 kg C-CO₂ ha⁻¹ y⁻¹ within the European regions. Climate projections showed variation up to ± 2800 kg C-CO₂ ha⁻¹ y⁻¹ from the historical values, identifying a tendency to store less CO₂ towards the first half of the century, especially for the Mediterranean regions. CO₂ stock is further reduced in central European latitudes towards the end of the century for RCP4.5 scenario, and came to a strong reduction on all regions during RCP8.5. A total of -1865 kg C-CO₂ ha⁻¹ y⁻¹ (corresponding to -338 Tg C-CO₂ y⁻¹) were stocked during the historical period. This amount raised in the first half of the century to -1845 kg C-CO₂ ha⁻¹ y⁻¹ (-336 Tg C-CO₂ y⁻¹) for RCP4.5 and -1859 kg C-CO₂ ha⁻¹ y⁻¹ (-339 Tg C-CO₂ y⁻¹) for RCP8.5. In the second half of the century NEP emissions assumed a further increase for both climatic scenarios to -1771 kg C-CO₂ ha⁻¹ y⁻¹ (-321 Tg C-CO₂ y⁻¹) for RCP4.5, and -1620 kg C-CO₂ ha⁻¹ y⁻¹ (-293 Tg C-CO₂ y⁻¹) for RCP8.5.

NGHGE indicated a potential capacity of the European production systems to store an average of -1155 ± 82 Tg C-CO₂eq y⁻¹ during the historical period (Table 2). N₂O and CH₄ were able to offset the NEP by 6.2 % and 0.8 %, respectively. In the first half of the century, the NGHGE assumed a slight reduction for RCP4.5, indicating a potential C stock, whereas remained substantially unvaried for RCP8.5. In the second part of the century NGHGE increased for both RCP4.5 (-1087 ± 119 Tg C-CO₂eq y⁻¹) and RCP8.5 (-997 ± 159 Tg C-CO₂eq y⁻¹), indicating a slowdown of C accumulation. Irrigation scenarios highlights an increased potential of C stock of about 3-4 %, mainly due to the greater NEP values. NGB indicated losses from European agricultural surfaces in the range of 236 ± 107 Tg CO₂eq y⁻¹ for the historical period (Table 2). Losses increased both in the first and the second half of the century and for both climate scenarios, being higher for RCP4.5 than RCP8.5.

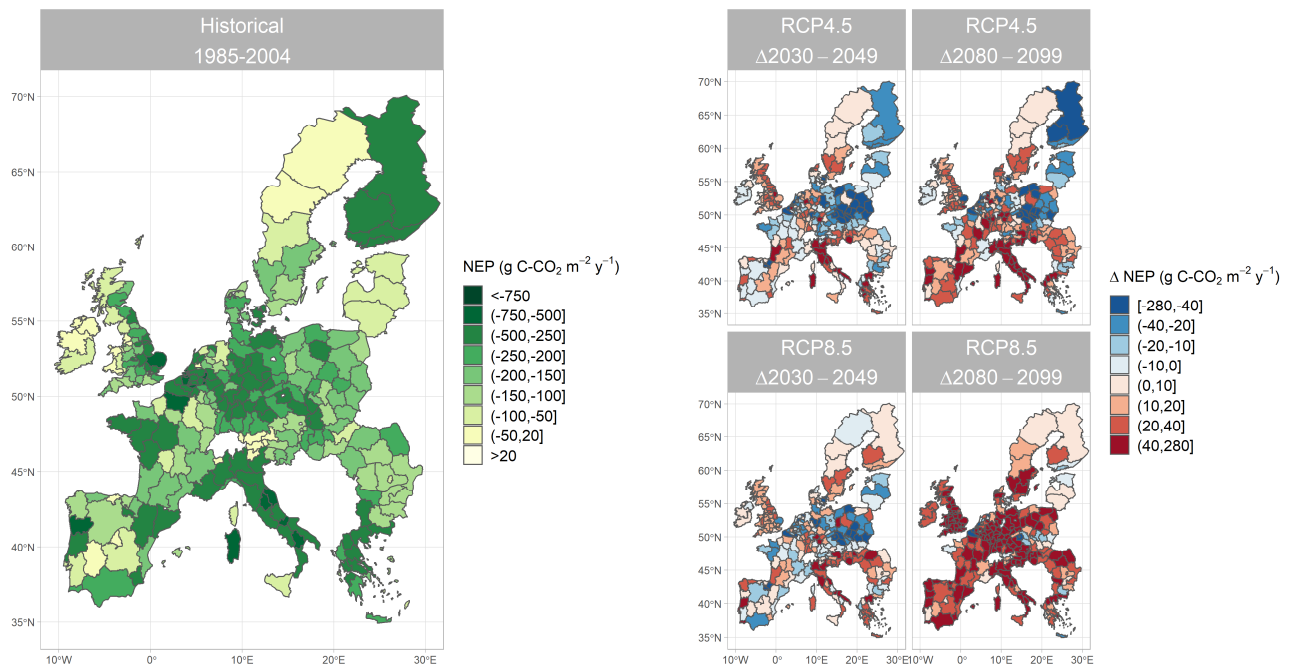

Figure 11: Net ecosystem production (NEP) for croplands and grasslands in European administrative borders (NUTS2). Results are reported for historical period (1985-2004), and difference “ Δ ” with mid (2030-2049) and the end of the century (2080-2099) for the two climatic scenarios RCP4.5 and RCP8.5. NEP for croplands is reported with irrigable scenario (see the text).

Table 2: The net greenhouse gas exchange (NGHGE) and net greenhouse gas budget (NGB) in EUROPE during the historical and two climate change scenarios. The elements of the budget are reported: N₂O, CH₄ and the net ecosystem production (NEP; for signs convention, negative values represent a stock of carbon). Results are in Tg CO₂eq y⁻¹. Between brackets is standard deviation.

Scenario and Period	N ₂ O	CH ₄	NEP	NGHGE	Harvest	Residues Exported	Fertilisation and dung	NGB

4 Discussion

4.1 Productions

Results from this study confirmed that the effects of climate change, implying shift of temperature, precipitation, and plant growing length among other factors, represents a serious drawback to plant production.

Air Temperature: Our findings pointed out that the increase of air temperature during the climate scenarios were negatively correlated with productivity, leading to a persistent reductions of biomass production in both grassland and croplands. This behaviour is confirmed also by previous studies (*e.g.* Challinor et al., 2014; Lobell and Tebaldi, 2014; Olesen and Bindi, 2002; Zhang et al., 2017), and was more pronounced for the more pessimistic climate scenario (-0.15 and -0.29 t DM ha⁻¹ y⁻¹ °C⁻¹ for RCP4.5 and RCP8.5, respectively, in the 2050-2099 period). Effects of air temperature in the European crop yields ranges from +5 % to -11 % for every degree of rising temperature for both climatic scenarios (remaining negative along most of the climate projected scenarios: -1 % and -5 %, for RCP4.5 and RCP8.5, respectively in the period 2025-2099), as also reported by recent studies using modelling and multi-modelling approaches (*e.g.* Asseng

560 et al., 2015; Bassu et al. 2014; Zhao et al., 2017; Yang et al., 2019). The extension of irrigable areas to all European
croplands reduce the dependence of daily maximum and minimum air temperatures on crop production (Fig. S8). This
demonstrates the fact that even with access to water (no limitation in irrigation), biomass production will decline due to
increasing air temperatures, as reported by Minoli et al. (2019). This can be seen also from biomass projections in Fig. 2,
565 considering an increase in temperatures over time. Interestingly, grassland productivity assumed a less pronounced
correlation with air temperature during climate scenarios compared to croplands (Fig.12). RCP8.5, characterised by a strong
reduction of grassland productions in the second half of the century, has an evident negative correlation with minimum and
maximum daily air temperatures ($r = -0.6$, $p < 0.01$), up to a null correlation under RCP4.5. Furthermore, crop yields were
strictly correlated with minimum and maximum air temperatures ($r = 0.64$ and $r = 0.57$, respectively; $p < 0.01$) compared
to grasslands, which did not show such a dependence ($r = 0.1$ for both minimum and maximum air temperatures),
570 highlighting a greater sensitivity of CERES-EGC model to air temperatures compared to PaSim.

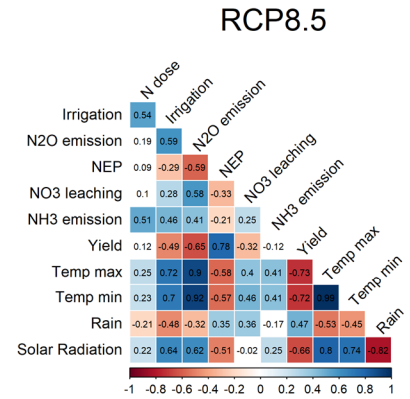

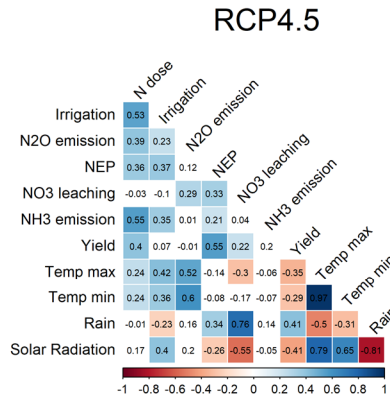

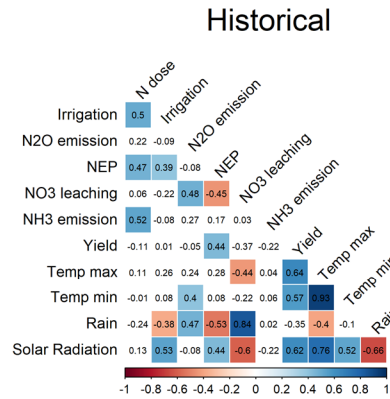

Precipitation: Results confirmed that rainfall have a positive effect for both crop ($r = 0.41$ and 0.13 for RCP4.5 and
RCP8.5, respectively; $p < 0.01$) and grassland production ($r = 0.26$ in RCP8.5, $p < 0.01$; null for RCP4.5). Compared to
the historical period, a reduction of precipitation was foreseen in the first half of the century for both scenarios (-2.1 mm
 y^{-1} for RCP4.5 and -0.74 mm y^{-1} for RCP8.5; $p \ll 0.01$) whereas in the second half of the century rainfall increases in
575 RCP4.5 ($+1.2$ mm y^{-1} ; $p \ll 0.01$) and decreases in RCP8.5 (-0.59 mm y^{-1} ; $p \ll 0.01$). This effect was more pronounced
for low latitudes (-1.2 and -2.3 mm y^{-1} for RCP4.5 and RCP8.5, respectively; $p \ll 0.01$) compared to high latitudes where
the rainfall tends to increase during the century ($+0.26$ and $+0.1$ mm y^{-1} in RCP4.5 and RCP8.5, respectively, respect to the
historical period; $p < 0.5$). These expected reduction in cumulated precipitation, will negatively affect productivity with
climate change scenarios, as confirmed by Hsu et al. (2012) for grasslands and by Olesen et al. (2011) for croplands.

580 **Length of crop growing cycle:** Apart from increases in temperature and reduction in precipitation, our simulation
highlights that crop yield is affected by the shortening of the length of the growing cycle, as confirmed by Tao and Zhang.
(2011), and Bassu et al. (2014). Bassu et al. (2014) predicted a general reduction of growing cycle length for maize in
central Europe with the multi-model assessment, de Souza et al. (2019) forecasted a reduction of 6 to 22 days for maize
cultivation in RCP4.5, and up to 8 to 29 days in RCP8.5 for Brazil conditions by using DSSAT/CERES-Maize. Moreover,
585 the consistent reduction of maize productions observed with the climate scenarios are mostly due to the shorter growing
period, characteristic of the spring crops. The magnitude of reduction of the length of growing cycle for wheat is consistent
with Yang et al. (2019) for the Mediterranean area which forecasted up to -26 days, compared to -22 days of our
simulations. Our findings confirm that climate change will have a regionally distributed impact (Howden et al., 2007;
Challinor et al., 2014; Parry et al., 2005; Lobell and Tebaldi, 2014) even in scenario that include mitigation measures to
offset climate change (RCP4.5), creating the possibility to the design cropping systems with multiple crops in a year-
590 Multiple cropping can be a viable alternative in regions with long growing seasons where water (rain or irrigation) and
solar radiation are not limiting factors (Mueller et al., 2015; Waha et al., 2020), as well as cardinal temperatures for crop

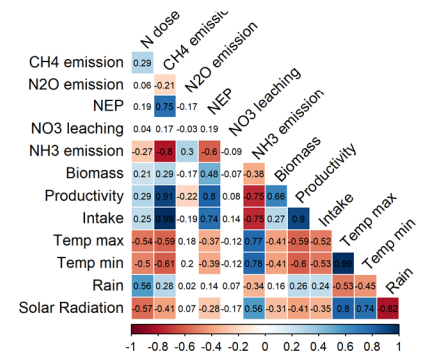

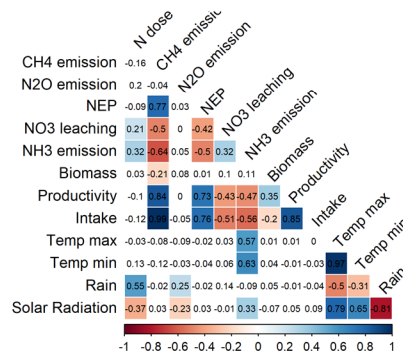

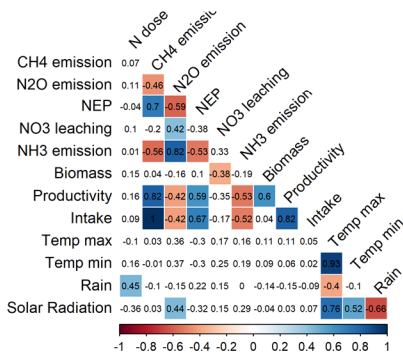

and varieties are met. Furthermore, a certain number of crops can be cultivated in the Europe even in the worst climate scenario and can potentially yield higher productions than today at high latitudes, while a whole reduction in crop production is expected for low latitudes.

595

Croplands

Grasslands

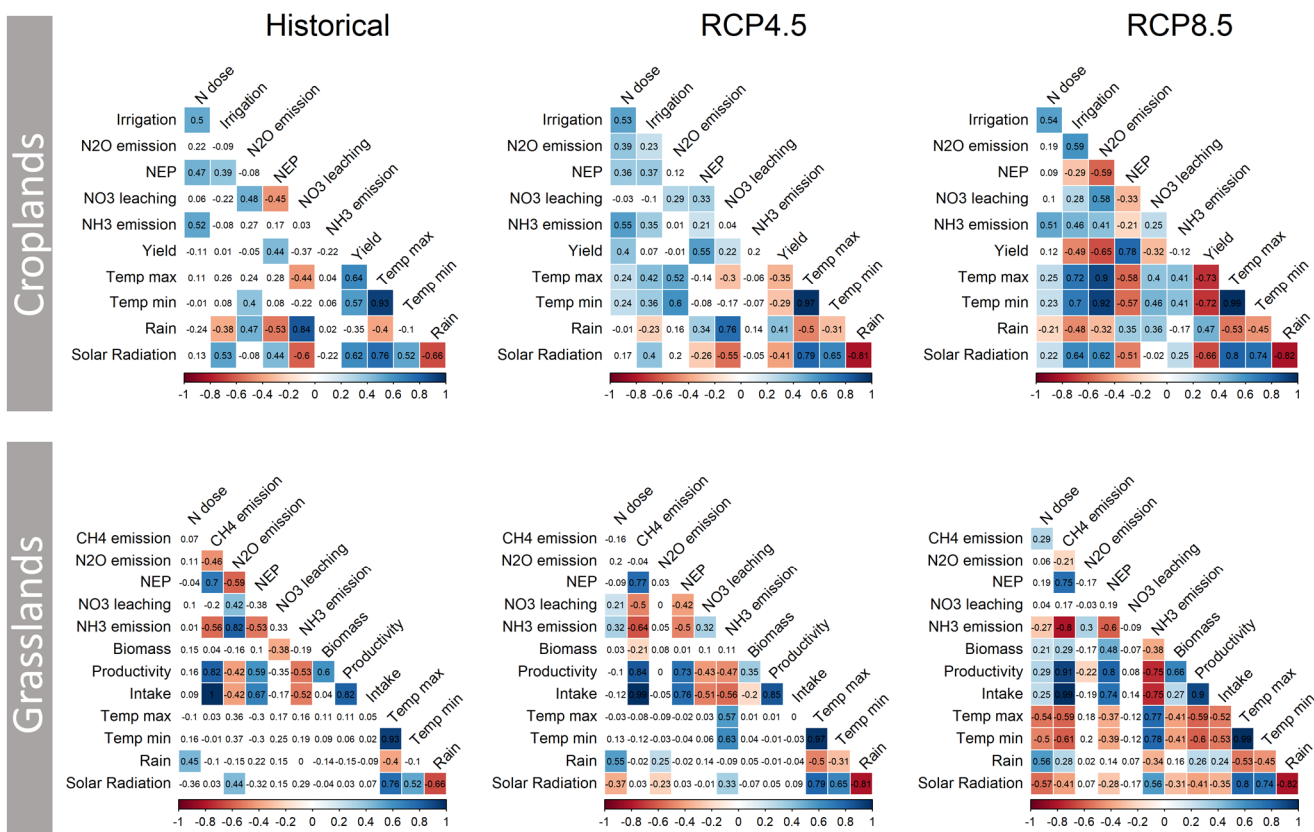

Figure 12. Correlation matrixes for croplands and grasslands considering the most interesting indicators for the objectives of this study. Correlation is presented for the historical period (1978-2004) and for the RCP4.5 and RCP8.5 scenarios; for croplands is reported the irrigable scenario. The irrigated and irrigable scenarios are reported in Fig. S8.

Finally, as reported in the result for the historical data (chapter 3.1.1), the productions of cropland and grasslands are in line with available data and the recent, albeit scarce, literature, making this study coherent and representative. Regarding the climatic projections, our study predicted an average yield for croplands of 4.49 t DM ha⁻¹ y⁻¹ (ranging from 3.55 to 5.49 t DM ha⁻¹ y⁻¹) in the period 2015-2099 with the RCP4.5 scenario, which is in line with the previous estimated yields reported by Lugato et al. (2018) of 4.34 t DM ha⁻¹ y⁻¹ (ranging from 3.69 to 4.90 t DM ha⁻¹ y⁻¹) for the same period and climate scenario by using DayCent model.

Assessing the effects of climate change in the European croplands and grasslands, our study gives a support for the identification of climate smart practices. Among these, the modulation of crop sowing dates or the implementation of irrigation, represent possible solutions in the short to medium term to prevent water stress (Lehmann et al., 2013).

Sowing date: Shifting sowing dates represents a promising adaptation to overcome yield drop (Olesen et al., 2012). Accordingly, our results showed that earlier sowing dates are expected for spring-sown crops under future climate scenarios, compared to historical dates. Differences between historical and future sowing dates ranged from 0 to -5 days for both RCP4.5 and RCP8.5 scenarios towards 2050, whereas at 2100 horizon earlier sowing dates are predicted with differences of -5 and -7 days for RCP4.5 and RCP8.5, respectively. This clearly shows that the climate change allows significantly more advanced sowing in Europe, as confirmed by Tubiello and Rosenzweig (2008). For winter-sown crops, sowing dates extended in a range from +5 to +9 days toward 2050, to +13 days in the end of the century for RCP4.5. These increases raised in RCP8.5, ranging from +7 to +13 toward 2050 and reaching +19 days on the way to 2100. The extension of irrigation in all simulated crops in Europe had a negligible influence on the length of the crop cycles, as discussed by Minoli et al. (2019), despite an increasing demand of water over the course of the century.

Irrigation: Water demand has been shown to increase by +6 %, during the first half of the century, to slightly decrease in its second half for RCP4.5 (-2 %) and increase again for RCP8.5 (+23 %) scenario. These changes are in line with the results of the multi-model approach used by Wada et al., (2013) analysing the uncertainty of the response of different hydrological models over Europe. Wada et al (2013) showed a decrease in water demand for irrigation toward 2100 of <5 % for RCP4.5, and a rise of >20 % for RCP8.5 in Europe. Furthermore, from our study we observed that water demand would assume a strong regionally variation in Europe, with low latitudes needing 227 mm y⁻¹ on average in the historical period (mean 1985-2004), an order of magnitude higher, respectively, than mid latitudes (29 mm y⁻¹) and high latitudes (9 mm y⁻¹). These proportions between the latitudes remained unvaried over the course of the century, whereas mid and high latitudes displayed a 20 % increase of water demand towards 2050 (mean 2030-2049) compared to historical period, in both climate scenarios. This phenomenon for low latitudes is strictly related to climate perturbation (*i.e.* strong increase of air temperature and reduction of rainfall), which increased crop water demand (Olesen et al., 2011). Furthermore, the potential increase of water demand even in mid and high latitudes, confirm that irrigation need to be supplied even for the crops that are now commonly rainfed (*e.g.* spring and winter soft wheat, spring barley, sunflower, rapeseed). Towards 2100, the water volumes needed for European croplands were largely reduced to under the amounts observed during the historical period, especially for low latitudes. These findings underline that even with high availability of irrigation water, the reduction of the crop growing cycle for the actual crop varieties, which sharpens toward the end of the century, is decisive to determine drops of yields. This is more evident for grain maize, the most water-demanding crop (Fig. 3), which needs an additional +35 mm y⁻¹ (average over Europe) to support production toward 2050, compared to the historical period. Towards 2100 water demand for maize remains identical to the historical period for RCP4.5, while increased (+25 mm y⁻¹) for RCP8.5. Conversely, water demand for winter soft wheat remained constant along the century for both RCP4.5 and RCP8.5 scenarios, whereas *i_RCP4.5* and *i_RCP8.5* scenarios confirmed an increasing water demand of about 50 mm (average over Europe; Fig. 3), as confirmed by Yang et al. (2019) for the Mediterranean regions.

4.2 Effect of climate on N₂O and CH₄ emissions

645 Emission of non-CO₂ GHG such as N₂O and CH₄ from enteric fermentation are strictly related to the trend of biomass
productions (Maaz et al., 2021).

N₂O. The estimation and the projection of N₂O emissions in the historical and the climate change scenarios were in line
with other model integrations over Europe. Lugato et al. (2017) estimated averaged emissions ranging from 1.18 to 2.63
kg N-N₂O ha⁻¹ y⁻¹ in the period 2010-2014 for both cropland and grasslands production systems with the DayCent model.
650 In comparison with Lugato et al. (2017), we found similar results for the Mediterranean latitudes (about 1 kg N-N₂O ha⁻¹
y⁻¹), while we predicted significantly lower emissions for Central Europe (1.1 kg N-N₂O ha⁻¹ y⁻¹, this study), as well as at
higher latitude (0.96 kg N ha⁻¹ y⁻¹, this study), compared to 3 kg N-N₂O ha⁻¹ y⁻¹ forecasted by Lugato et al. (2017). Indeed,
lower emissions at high latitudes were also reported by other studies (World Bank; Eurostat, 2017; Stehfest and Bouwman,
2006; Wells et al., 2018). Other research in the field were also within the range of our results *e.g.* Reinds et al., (2012)
655 estimated emissions ranging from 1.1 to 2.4 kg N-N₂O ha⁻¹ y⁻¹ for arable lands for the year 2000, de Vries et al. (2011)
0.27 and 0.38 Mt N-N₂O y⁻¹ for fertilizers and manure, and from grazing, respectively. Recently estimation by Eurostat
(2017) reported values of 0.39 Mt N-N₂O y⁻¹ (184.8 Tg CO₂eq) for the year 2015, based on lower Tier methodology, while
our study reports lower values equals to 0.17 Mt N-N₂O y⁻¹ (80 Tg CO₂eq) for the same year. Tian et al. (2020) reported
emissions from EU agriculture based on global inventories in the order of 0.51 Mt N-N₂O y⁻¹ in the decade 2007-2016,
660 significantly higher than those found in our study (0.17 Mt N-N₂O y⁻¹) for the same period. In addition, the estimation by
Tian et al. (2020) included also manure management and aquaculture, and suffers from high uncertainties given by the
quality of the data and statistics used as input and, foremost, by the use of default emission factors. Regarding climate
projection studies, Lugato et al. (2018) quantified N₂O emissions for croplands in the RCP4.5 scenario, reporting losses of
1.81 and 1.77 kg N-N₂O ha⁻¹ y⁻¹ for the first and the second part of the century, respectively. These estimations resulted
665 comparable, while slightly higher, to the emissions for croplands issued from our study, both for the first part of the century
(1.53 ± 0.23 kg N ha⁻¹ y⁻¹) and for the second (1.66 ± 0.28 kg N ha⁻¹ y⁻¹). Our study highlighted that crop type is a significant
determinant of N₂O EFs of fertilisers, with most of the cereals having low EF (barley, fodder maize, soft spring wheat and
rapeseed; mean = 1.1 %), and pulses, soybean and potato a high (mean EF = 3.1 %), during 1985-2004 integration period.
The highest EF for leguminous crops indicates that the management of fertilisation for these crops, or for the rotation itself,
670 can be improved on the input data. Finally, information about crop-specific EF turns to be useful to design crop successions
and compiling emission inventories (Myrgiotis et al., 2019). However, our results were higher than the 1 % default value
defined by the IPCC guidelines for the N applied to agricultural soils, mainly because we consider only the N applied as
fertiliser, neglecting animal excretions, crop residues, deposition, mineralization and fixation. Anyway, this default factor
shows large uncertainties at local to regional scales, especially for agricultural N₂O emissions, due to the scarce captured
675 dependence of emission factors on spatial diversity of management, pedoclimatic, soil physical and biochemical conditions
(Leip et al., 2011; Reay et al., 2012; Shcherbak et al., 2014; Cayuela et al., 2017). We observed that N₂O emitted from

croplands had a significant and positive correlation ($p < 0.05$) with rainfall ($r = 0.47$), as well as minimum and maximum air temperatures during the historical period (Fig. 12). The correlation with the minimum and maximum air temperatures increased ($p < 0.01$) depending ~~ofon~~ the climatic scenarios ($r > 0.5$ for RCP4.5 and $r > 0.9$ for RCP8.5; Fig. 12), while the relation with rain turned to negative for RCP8.5 ($r = -0.32$, $p < 0.01$). This trend inversion is probably connected to the strict dependency of N₂O emissions to the length of crop growing period rather than the yearly cumulated rainfall, which can occur outside of the cultivation period, as also stated by Shcherbak et al. (2014). Accordingly, the correlation from N₂O and the irrigation amount occurring during the cultivation period raised in the climate scenarios ($r = 0.23$ and 0.59 for RCP4.5 and RCP8.5, respectively; $p < 0.01$). The projected temperature rise in the climate scenarios has a latitudinal impact with N₂O emissions, which is directly correlated at mid- and high latitudes for croplands ($r > 0.5$ for RCP4.5 and $r > 0.9$ for RCP8.5; $p < 0.01$) and at low latitudes for grasslands ($r > 0.45$ for RCP8.5 and $r > 0.75$ for RCP4.5; $p < 0.01$). Precipitation in the mild climate has a direct influence on N₂O emissions ($r = 0.25$, $p < 0.01$) at mid-latitudes for both production systems, also at high latitudes for croplands. Precipitation is anticorrelated emissions in the RCP8.5 scenario at mid- and high-latitudes for croplands, and at low latitudes for grasslands. Moreover, N₂O emissions from cropland and grasslands were both positively correlated with soil clay content ($r > 0.5$, $p < 0.01$; data not shown) for values lower than 32 %, as higher clay content can promote complete denitrification (Weitz et al., 2001).

CH₄. Methane emissions in EU were mainly concentrated in the regions with the highest density of grazing animals (Vuichard et al., 2007). The range of the emissions simulated in this study were in line with the simulation of Chang et al. (2015), which found emissions of 18.7 ± 7.9 kg C-CH₄ ha⁻¹ y⁻¹ (period 1961-2010) and by Hörtnagl et al. (2018) by experimental trials from central European grasslands. Soussana et al. (2007) reported emissions over Europe higher than our study, 41 kg C-CH₄ ha⁻¹ y⁻¹ with comparable animal densities, as well as ~~Vuichard~~ Vuichard et al. (2007) with 108 kg C-CH₄ ha⁻¹ y⁻¹ using PaSim model, but with a higher stocking rate. CH₄ emissions decreased towards the end of the century, especially in the RCP8.5 scenario, due to reduced biomass productivity of grasslands that reduced animal intake (Fig. 2) and the stocking density, which is reduced to 8 % compared to RCP4.5 in the last decade of the century. Reduction of stoking density was also found by Chang et al. (2015). Furthermore, rising temperatures and reduced precipitations could be able to decrease the protein content and the digestibility of the forage, resulting in a possible reduction of N₂O losses from dung and urine in pastures. However, this mechanism could be compensated by in an increase of methane (CH₄) losses (Wilkinson and Lee, 2017).

Nitrogen Use Efficiency (NUE). We observed an increase in the NUE for the European croplands, especially for the mild climate change projection. Compared to the historical period, in the RCP4.5 scenario, there is a reduction in the correlation between N₂O emitted with the other N losses (NO₃ and NH₃) and crop yield (Fig. 12). Conversely, there is an intensification of the dependence with the N dose. In fact, with an identical amount of N applied in the rotations over the simulated years, both NO₃⁻ and NH₃ losses were reduced along the century (data not show), and crop yields increased, at least, until 2050. This indicated a potential increase in the NUE. Kanter et al. (2016) observed an increase of the NUE by 2050 due to the

710 increasing yields, support our findings. The improvement of NUE is a key factor to reduce environmental negative effects
and mitigating GHG emissions. Bouwman et al. (2013) indicated that NUE improvement could reduce N₂O emissions by
more than 30 % by 2050 in the RCP8.5 scenario. On the other hand, in the RCP8.5 scenario the correlation between N₂O
emissions and N dose is lost ($p > 0.01$), and a strong negative ($p < 0.01$) score between yield and nitrogen losses took place,
715 indicating a reduction of NUE. This lack of relationship is most probably connected to the interannual variability of N₂O
emissions in the strongest scenario and in the second part of the century. Higher NUE are typical for low European latitudes
than mid and high latitudes, since yields are generally higher and the N losses lower (Sutton et al., 2011). Improving actual
agronomic practices to improve NUE could have several benefits. These practices can increase crop yields and reduces
reactive N losses, including N₂O emissions (Lassaletta et al., 2014; Myrgeiotis et al., 2019). In this context, irrigation
represents a fundamental intensification practice to counteract the effects of climate change in crop productions (Minoli et
720 al., 2019). In our case, the extension of the irrigation to all cropping systems in EU significantly decreased N losses as (-5
% for NO₃ leaching and -4 % for NH₃ emissions, on average, for both i_RCP4.5 and i_RCP8.5 scenarios), and increased
crop yield (Fig. 2), leading to a potential increase in the NUE.

Concerning grasslands, we noted weak relationship between N₂O emissions and N application doses. This is mainly due
to the calculation of N doses and management as a function of animal loads, fraction of leguminous, mowing events and
725 available amount of mineral fertilizers and / or organics. During the historical period, N₂O emissions were positively
correlated with NO₃ and NH₃ losses and negatively correlated with productions, representing a potential low NUE.
Moreover, N₂O emissions in grassland were anti-correlated with CH₄ emissions. CH₄ emissions are rather positively related
to biomass production and livestock intake. Therefore, low biomass production could potentially increase N₂O emissions,
due to low NUE, and can decrease CH₄ losses, due to low livestock intake. Surprisingly, N₂O emissions in grasslands were
730 weakly correlated with meteorological variables, especially minimum and maximum air temperatures, whereas a relation
with rain and solar radiation is noticeable for RCP4.5, while is not evident for RCP8.5. As observed for croplands, the
relation between N₂O and NH₃ emissions is positive, especially for the RCP8.5 scenario, to indicate a possible reduction
of the NUE.

4.3 Potential carbon stock

735 **NEP.** The NEP represents a simple indicator of carbon storage potential, since does not account for C removal in terms of
yield, animal intake or crop residues. Concerning cropland, our results are directly comparable with Kutsch et al. (2010)
during the historical period who observed fluxes of $-2400 \pm 1130 \text{ kg C-CO}_2 \text{ ha}^{-1} \text{ y}^{-1}$ based on field measurements in
multiple sites in Europe (see Table 1), confirming a net potential storage of C. Regarding climate scenarios, a noticeable
decline of C uptake was predicted in north-western cropping systems (British islands, Scandinavian peninsula) and
740 Mediterranean area. This is most probably due, respectively, to the increase of soil heterotrophic respiration caused by
climatic factors, and to a potential reduction of NEP, as also reported by Kirschbaum (1995) (Fig. S9). Further decreasing
values of NEP (towards carbon stock) were evident in the central and in the north-eastern European, especially in the first

part of the century. A substantial increase of NEP in croplands was predicted towards the end of the century for the RCP8.5 scenario. This increase is most probably due to the low levels of heterotrophic respiration (*i.e.* microbial respiration due to soil organic matter decomposition processes) related to a partial soil coverage (*e.g.* no cover crops) of the simulated crop successions (Emmel et al., 2018). Conversely, in grasslands systems we observed lower averaged values compared to arable lands. This is related to the continuous biomass removal from grazers, the general higher content of SOC in the topsoil, the long-term land use (Morais et al., 2019), and the larger heterotrophic respiration that characterises these soils, especially if extensively managed (Bahn et al., 2008). These evidences were also described by Chang et al. (2015) who simulated an average of $-570 \text{ kg C-CO}_2 \text{ ha}^{-1} \text{ y}^{-1}$ between 1961 and 2010 for EU (close to $-622 \pm 62 \text{ kg C-CO}_2 \text{ ha}^{-1} \text{ y}^{-1}$ in the historical period from our study). In general, areas where the heterotrophic respiration is enhanced by climatic drivers or by high amount of SOC, would lead to lower values of NEP (Chang et al., 2017). This is the case for the north-east of France and the British islands, while for the Scandinavian peninsula and north-east Europe, characterised by low C and low heterotrophic respiration, NEP reached higher values. These findings point out that in view of a growing productivity expected towards 2050, storing additional (new) carbon will be more challenging in areas characterised by high levels of SOC (Hassink and Whitmore, 1997), mainly due to high levels heterotrophic respiration. Finally, grasslands remained a potential sink for C during the historical period, which was in line with experimental measurements performed in the last two decades, *e.g.* $-2470 \pm 670 \text{ kg C-CO}_2 \text{ ha}^{-1} \text{ y}^{-1}$ reported by Soussana et al. (2007), and -25 to $-486 \text{ g kg C-CO}_2 \text{ ha}^{-1} \text{ y}^{-1}$ reported by Hörtnagl et al. (2018). However, our results were slightly higher in absolute value than the mean value simulated by Chang et al. (2015) from 1961 to 2010 ($-570 \pm 210 \text{ kg C-CO}_2 \text{ ha}^{-1} \text{ y}^{-1}$).

N₂O emissions from croplands were able to offset (reduce) the C sequestration potential. Offsets were in the order of 5.4 % for the historical period, and up to 6.1 % and 7.5 % in the end of the century for RCP4.5 and RCP8.5, respectively. The extension of irrigation to all European arable lands reduced these gaps, mainly due to the increase values of NEP (5.4 % and 7.1 % for *i*_RCP4.5 and *i*_RCP8.5). Few data are available in the literature regarding the CO₂ storage potential for croplands (Emmel et al., 2018). Our results confirmed that croplands may act as a potential sink of C when ignoring C exports by harvest (Buysse et al., 2017; Ceschia et al., 2010).

N₂O and CH₄ emissions in grasslands were able to offset NEP during the historical period by 17 % and 1 %, respectively. These results are compatible with the studies reported by Soussana et al. (2010) who displayed offsets over EU of 34 % and 10 % for N₂O and CH₄, respectively. During climate projection, the offset rises to 22 % for N₂O and 1.2 % for CH₄ towards 2050 for both RCP4.5 and RCP8.5. In the second part of the century N₂O emission offset the potential carbon sequestration by 26 % and 52 % for RCP4.5 and RCP8.5, respectively, while CH₄ offsets varied between 1.2 % and 1.9 % for RCP4.5 and RCP8.5, respectively.

4.4 GHG emission budget

For both cropland and grasslands, CO₂ storage potential (estimated from NEP) provided the largest term in the net greenhouse gas exchange ~~balance~~-(NGHGE), confirming the statement by Jones et al. (2016). The NGB, calculated ~~asby subtracting~~ the

780 ~~balance between NGHGE and other non-gaseous C forms fluxes (i.e. export by harvest, manure and crop residues), import by~~
~~manure) from NGHGE~~, indicated that European agricultural surfaces are a net C source. The most important components that
determined these losses were the C exports, yield ($F_{C\text{-harvest}}$) and crop residues ($F_{C\text{-residues}}$), which varied proportionally to the
NEP in the various climatic projections, *i.e.* the lower the NEP, the lower the yields. The non-CO₂ GHGs, despite being high
785 especially in the RCP8.5 scenario towards the end of the century, had a minor impact in the differentiation of the two climatic
scenarios, although they represent an important component in the overall carbon balance at the European level (see Table 3).
The values observed for NGB highlight that C inputs into the system such as organic fertilizers (the manures used in this study
have a C:N ratio of 25 and represent 2/3 of the component $F_{C\text{-manure}}$), or actions aimed to recycle a portion of biomass in the
field (crop residues management), are essential to improve the overall C budget toward a net storage, as reported by Ceschia
790 et al. (2010) and Buysse et al. (2017). Moreover, our findings shown that the contribution of crop residue roughly corresponded
to the carbon deficit in Europe. Therefore, crop residue could play a key-role in land-based mitigation of anthropogenic
emissions, as also reported by Stella et al. (2019). This is in line with the “4 per 1000” initiative (Rumpel et al., 2019) promoting
the maintenance of soil fertility as a key to achieve GHG mitigation strategies. In addition to the spatial diversity observed on
the European agricultural area, the achievement of this goal depends on the complexity of rural, economic, and political
795 structure of the territories (Amundson and Biardeau, 2018). Furthermore, local policies can be supported by simulation tools
as used in this study, bearing in mind that their effectiveness can be affected by the omission of large variances given by varied
characteristics of small extents. Finally, irrigation management extended to all European cropping land is able to increase the
stored C (NEP = -3 %), but increases the contribution of $F_{C\text{-residues}}$ and the non-CO₂ GHG (up to +4 %), leading to slightly
higher C deficits.

795

4.5 Uncertainty, limitations and novelty

The extension of field-scale models to a regional scale faces several challenges associated with the representation of the
systems under study, which can affect the confidence of the model outputs (Challinor et al., 2014; Folberth et al., 2019).

1. **Input data** requirement for such models for large and heterogeneous areas are difficult to fulfil (Therond et al.,
800 2011). ~~Soil~~While soil and climate inputs are directly available from European databases at different spatial
resolutions. ~~Details, details~~ on crop and grassland management (*e.g.* type and amount of inputs, timing of operation,
tillage system, crop varieties) are less readily available and ~~are~~represent an important source of uncertainty (Molina-
Herrera et al., 2016). In our assessment we used a dataset for cropland, ~~with constituted by statistical~~ data of crop
rotations resulting from a spatial ~~crop cultivation~~ distribution (~~of crops at NUTS2~~) scale and by crop succession
805 likelihoods, on a high-resolution scale (1 km). ~~For instance, this × 1 km~~. This dataset ~~does not report~~include details
about management or crop growth parameters. The absence of plant phenological development data, ~~constitutes for~~
instance, is a relevant source of uncertainty in regional assessments (Minoli et al., 2019) ~~since they affect~~. This

810 information defines crop growth and the length of growing length, theseason, influencing biogeochemical cycles at different scale and arebecame key for future projectionprojections. To deal with this lack of information, we calculated crop-specific sowing and fertilisation dates as a function of climate (Ramirez-Villegas et al., 2015), together with the uses of different crop varieties following a latitudinal gradient to fulfil the thermal units needed, N doses and the crop-specific residue management, aiming to reduce the uncertainty of input data (Hansen and Jones, 2000). Furthermore, the use of two different crop rotations per simulation unit attempt to cover a range of uncertainties existing below the spatial resolution of 0.25°, which, however, cannot be assumed to be fully covered by the range of setups presented here. Another limitation of this and other regionalized studies is the deviation in the representation of the quantities within the administrative units, which is related to the scarcity of management data with fine spatial resolution. For example, the amounts of fertiliser to be distributed on cropping systems, which are provided at a regional level, show little heterogeneity within the boundaries of the region itself, and can mark a sharp transition between adjacent regions. In the present work CERES-EGC model used fixed parameters issued from a calibration over different sites in EU (Lehuger et al., 2010; Lehuger et al., 2011; goodness of fit, $R^2 = 0.59$ to 0.76 for NEP; error of prediction reduced by 6-40% for N_2O compared with the model's standard parameters). Grasslands, as previously reported, were simulated with a parameter set resulting from a multi-site calibration for a network of EU grasslands (*i.e.* flux tower network, see Ma et al., 2015; goodness of fit, $R^2 = 0.4$ to 0.9). Likewise, PaSim follows an adaptive management based on climate. Since the information concerning the input data are already the result of a scaling process, we retain 825 that an uncertainty analysis concerning the input data is not appropriate (Hansen and Jones, 2000).

2. **Calibration of models:** to fulfil this task over large areas, data representing the spatial and temporal variation of models' parameters are required. Although both models have been calibrated and verified with direct observations under various pedo-climatic and management conditions at the field-scale, comprehensive studies aimed to calibrate these and other models with spatially extensive time series are still scarce (Balkovič et al., 2013; Lehuger et al., 2010; 830 Lugato et al., 2010; Vuichard et al., 2007). Data aggregation over the same extent can be used to assess model representations, even if they do not represent the field-scale conditions for which the models have been originally calibrated (Lugato et al., 2017; Therond et al., 2011; van der Velde et al., 2009), exposing themmodels to a broader range of conditions (*e.g.* weather and soil characteristics). Indeed, dealing with lacking and heterogeneous input data requires different procedures of downscaling and upscaling for the different data types, which potentially contribute 835 to feed the uncertainty of the representation. Consequently, projecting regional model responses under future climate scenarios requires careful understanding of input and model uncertainty (Asseng et al., 2013; Challinor et al., 2009). This is the reason why the two periods of temporal aggregation considered in the present study, historical and climate scenarios, provide outcomes with different levels of confidence. In the historical period, results are obtained based on the spatial aggregation of real (statistical) data by means of models parameterised with current soil, climate and 840 vegetation conditions. The outcomes of the climate scenarios deal with the uncertainty related to the sensitivity of the

model parameters and the algorithms to climate variables, which is expected to be different due to the diverging intensities of the two projections and the different conditions in the near- and the long-term (2100). For this reason, direct comparisons between the two aggregation periods should be done with caution.

3. **Model validation:** Data quality and availability prevent also the validation of regional scale models, even if literature report some effort (Challinor et al., 2009; Faivre et al., 2004; Niu et al., 2009). Comparing the model outputs with statistical data aggregated at regional scale (productions) allowed to obtain indications about the magnitude of simulated variables at the same spatial extent. Furthermore, assessing the ranges of the model outputs, *e.g.* yield, with measured data and over EU ($r = 0.92$, $p < 0.01$ for croplands, Fig S1; $r = 0.68$, $p < 0.05$ for grasslands, Fig 1), as well as other modelling interpretations (even if grounded on different approaches), contributed decidedly to increase the reliability of our estimations.

~~Finally, literature~~Literature reports similar studies aiming to estimate crop and/or grasslands productions, GHG emissions and carbon storage at regional scale (Chang et al., 2017; Lugato et al., 2018; Blanke et al., 2018). ~~Compared to them, the novelty introduced by this study grounds on the combination of two specific models for the systems under study, for the detailed and dynamic management options (Leip et al., 2008; Lugato et al., 2017) and for the finer spatial resolution (Ciais et al., 2010; Iglesias et al., 2012; Lugato et al., 2014; Vuichard et al., 2007). Moreover, albeit aggregated in~~European scale Lugato et al. (2014), based on EU statistics, constituted a database of soil, climate and land use for grassland and cropland to simulate SOC with CENTURY model, which worked at monthly time step. Subsequently, this dataset was improved with direct soil observation network over Europe to estimate N₂O emissions from cropland with the DayCent model, at daily and the long-term resolution (Lugato et al., 2017). These Authors finally used an interesting method to fill and upscale the simulated results by means of a meta-model, however adding an additional source of uncertainty. Regarding grasslands, Chang et al. (2015) used ORCHIDEE-GM model, which contains the management equations derived from PaSim, to simulate the greenhouse gas balance in Europe, recently expanding their analysis with climate scenarios (Chang et al., 2017). Blanke et al. (2018) improved the LPJ-GUESS global model to be applied for grasslands and estimate carbon and nitrogen balance with future climate. Compared to them, this study combined two state-of-the-art models specific for the systems under study producing both separated and joint results on croplands and grasslands. The novelty of this work is based on the use of a dynamic management with specific crop rotations, instead of exploring one or a few specific crops (*e.g.* Sansoulet et al., 2014, Yang et al., 2019). Moreover, our assessment was conducted at finer spatial resolution than *e.g.* Vuichard et al. (2007) with the PaSim model, or Leip et al. (2008) with DNDC, and agrees with the resolution used by Chang et al. (2015) for grassland, although studies at an ever finer spatial scale have recently been proposed on France with the STICS model (Launay et al., 2021). Albeit aggregated in gridded simulation units, our work considers a variety of pedoclimates over EU and is not based on an extrapolation of a few points or on a single European area (Ceschia et al., 2010; Kutsch et al., 2010; Myrogiotis et al., 2019; Soussanna et al., 2010). ~~Knowing~~

875 Finally, knowing and controlling the sources of uncertainty from regional applications could be a key to the improvement of decision-support tools for the design of policies. In this context, providing a range of possible outcomes, the application of multi-model ensemble (Ehrhardt et al., 2018; Martre et al., 2015; Sándor et al., 2018; Rosenzweig et al., 2013) at regional scale, could represent a valuable tool to tackle this source of uncertainty. Increasing spatial resolution of the input dataset we used (*e.g.* weather and management data) could represent also a key to further reduce uncertainties from input data in future large-scale applications (Folberth et al., 2019; Hoffmann et al., 2016; Stella et al., 2019).

5 Conclusions and perspectives

880 In this study we presented the combined spatial analysis of two specific models for crops and grassland, to quantify the effects of climate change on the European agricultural systems. Results clearly showed that the productions will be stable in the first half of the century, while a strong reduction will occur during the second half of the century, especially at low latitudes, and mainly due to a reduction in the length of growing cycle. Non-CO₂ greenhouse gas emissions were triggered by the rising temperatures, increasing significantly in the second part of the century. At the EU scale, both grasslands and croplands are potential carbon sinks, although this potential is reduced by the negative effects of climate change on productivity. Biomass removal from the agricultural surfaces (yield, hay and hay animal intake), combined with the animal intake and the removal of crop residues, transformed shift the production systems into balance towards a net source of carbon loss. In this framework, the introduction of carbon with fertilizers and dung was not able to counterbalance these removals of C. Crop residues restitution could be a potential strategy to improve the overall carbon balance towards a C neutrality, or even towards a C storage. The positive effects of crop residues recycle restitution on N₂O emissions carbon and the net greenhouse gas balance need to be investigated with further researches. Our study highlights that storing further carbon in areas characterised by high levels of SOC will be more challenging in the future. The extension of irrigation to all European croplands highlights a significant increase of water demand over the next few decades for most of the European croplands, whereas the benefit in terms of crop yield will not contribute substantially to fill the gap of carbon losses.

895 Our findings show that productivity, GHG emissions and changes in soil C-stock have a heterogeneous spatial distribution. This underlines the need of targeted agricultural policies at territorial scale aimed to avoid the risk of significant reductions of productivity and mitigate the negative effects of climate change, foremost expected in the second half of the century. Accordingly, this transformational adaptation has to deal with socio-economic and political dynamics, as well as land suitability (Fischer et al., 2005; Chaudhary et al., 2018, Martin-Lopez et al., 2019). This work provides a database on cultivation and management of cropland and grassland at a detailed spatial level, which. Data can be improved to reduce uncertainty and exploited in future work to test different management options, new or a combination of agro-ecosystem models, climate change projections, crop varieties or floristic compositions, and the support for future actions.
