Abstract. Apparent temperatures (AP) and ground level aerosol pollution (PM_{2.5}) are important factors in human health, particularly in rapidly growing urban centres in the developing world. We quantify how changes in apparent temperature – that is a combination of 2 m air temperature, relative humidity and surface wind speed, and PM_{2.5} concentrations – that depend on the same meteorological factors along with future industrial emission policy, may impact people in the greater Beijing region. Four Earth System Models (ESM) simulations of the modest greenhouse emissions RCP4.5, the “business-as-usual” RCP8.5 and the stratospheric aerosol injection G4 geoengineering scenarios are downscaled using both a 10 km resolution dynamic model (WRF), and a statistically approach (ISIMIP). We use multiple linear regression models to simulate changes in PM_{2.5} and the contributions meteorological factors make in controlling seasonal AP and PM_{2.5}. WRF produces warmer winters and cooler summers than does ISIMIP both now and in the future. These differences mean that estimates of numbers of days with extreme apparent temperatures vary systematically with downscaling method, as well as between climate models and scenarios. Air temperature changes dominate differences in apparent temperatures between future scenarios even more than they do at present because the reductions in humidity expected under solar geoengineering are overwhelmed by rising vapor pressure due to rising temperatures and the lower windspeeds expected in the region in all future scenarios. Temperature and humidity differences between scenarios change the relative risk of disease from PM_{2.5} such that G4 results in 1-3% higher health risks than RCP4.5. Urban centres see larger rises in extreme apparent temperatures than rural surroundings due to differences in land surface type, and since these are also the most densely populated, health impacts will be dominated by the larger rises in apparent temperatures in these urban areas.

500 character non-technical text

Apparent temperatures and PM_{2.5} pollution depends on humidity and wind speed in addition to surface temperature and impacts human health and comfort. Apparent temperatures will reach dangerous levels more commonly in future because of water vapor pressure rises and lower expected wind speeds, but these will also drive change

41 in PM_{2.5}. Solar geoengineering can reduce the frequency of extreme events significantly
42 relative to modest, and especially “business as usual” greenhouse scenarios.
43
44

45 **1. Introduction**

46 Global mean surface temperature has increased by 0.92°C (0.68-1.17°C) during 1880-
47 2012 (IPCC, 2021), which naturally also impacts the human living environment
48 (Kraaijenbrink et al., 2017; Garcia et al., 2018). However, neither land surface
49 temperature nor near-surface air temperature can adequately represent the temperature
50 we experience. Apparent temperature (AP), that is how the temperature feels, is
51 formulated to reflect human thermal comfort and is probably a more important
52 indication of health than daily maximum or minimum temperatures (Fischer et al., 2013;
53 Matthews et al., 2017; Wang et al., 2021). There are various approaches to estimating
54 how the weather conditions affect comfort, but apparent temperature is governed by air
55 temperature, humidity and wind speed (Steadman 1984; Steadman 1994). These are
56 known empirically to affect human thermal comfort (Jacobs et al., 2013), and thresholds
57 have been designed to indicate danger and health risks under extreme heat events (Ho
58 et al., 2016). Analysis of historical apparent temperatures in China (Wu et al., 2017; Chi
59 et al., 2018; Wang et al., 2019), Australia (Jacobs et al., 2013), and the USA (Grundstein
60 et al., 2011) all find that apparent temperature is increasing faster than air temperature.
61 This is due to both decreasing wind speeds and, especially to increasing vapor pressure
62 (Song et al., 2022).

63
64 As the world warms, apparent temperature is expected to rise faster than air
65 temperatures in the future (Li et al., 2018; Song et al., 2022). Hence, humans, and other
66 species, will face more heat-related stress but less cold-related environmental stress in
67 the warmer future (Wang et al., 2018; Zhu et al., 2019). Since most of the population is
68 now urban, the conditions in cities will determine how tolerable are future climates for
69 much of humanity, while the differences in thermal comfort between urbanized and
70 rural regions will be a factor in driving urbanization. Reliable estimates of future urban
71 temperatures and their rural surroundings require methods to improve on standard
72 climate model resolution to adequately represent the different land surface types;
73 especially the rapid and accelerating changes in land cover in the huge urban areas
74 characteristic of sprawling developments in the developing world. This is usually done
75 with either statistical or dynamic downscaling approaches, and in this article we
76 examine both methods.

77
78 In early 2013, Beijing encountered a serious pollution incident. The concentration of
79 PM_{2.5} (particles with diameters less than or equal to 2.5 μm in the atmosphere) exceeded
80 500 μg/m³ (Wang et al., 2014). Following this event and its expected impacts on human
81 health (Guan et al., 2016; Fan et al., 2021) and the economy (Maji et al., 2018; Wang

82 et al., 2020), the Beijing municipal government launched the Clean Air Action Plan in
83 2013. The annual mean concentration of PM_{2.5} in Beijing-Tianjin-Hebei region
84 decreased from 90.6 μg/m³ in 2013 to 56.3 μg/m³ in 2017, a decrease of about 38%
85 (Zhang et al., 2019), although this is still more than double the EU air quality standard
86 (25 μg/m³) and above the Chinese FGNS (First Grand National Standard) of 35 μg/m³.
87 The concentration of PM_{2.5} is related to anthropogenic emissions, but also dependent
88 on meteorological conditions (Chen et al., 2020). Simulations suggested that 80% of
89 the 2013-2017 lowering of PM_{2.5} concentration came from emission reductions in
90 Beijing (Chen et al. 2019). Humidity and temperature are the main meteorological
91 factors affecting PM_{2.5} concentration in Beijing in summer, while humidity and wind
92 speed are the main factors in winter (Chen et al., 2018). Simulations driven by different
93 RCP emission scenarios with fixed meteorology for the year 2010 suggest that PM_{2.5}
94 concentration will meet FGNS under RCP2.6, RCP4.5 and RCP8.5 in Beijing-Tianjin-
95 Hebei after 2040 (Li et al., 2016).

96
97 The focus here is in the differences in apparent temperature and PM_{2.5} that may arise
98 from solar geoengineering (that is reduction in incoming short-wave radiation to offset
99 longwave absorption by greenhouse gases) via stratospheric aerosol injection (SAI),
100 and pure greenhouse gas climates. We use all four climate models that have provided
101 sufficient data from the G4 scenario described by the Geoengineering Model
102 Intercomparison Project (GeoMIP). G4 specifies sulfates as the aerosol, and greenhouse
103 gas emissions from the RCP4.5 scenario (Kravitz et al., 2011). The impacts of G4 on
104 surface temperature and precipitation have been discussed at regional scales (Yu et al.,
105 2015) and both are lowered relative to RCP4.5. Some studies have focused on regional
106 impact of SAI on apparent or wet bulb temperatures: in Europe, (Jones et al., 2018);
107 East Asia (Kim et al., 2020); and the Maritime Continent (Kuswanto et al., 2021). But
108 none of these studies have considered apparent temperature at scales appropriate for
109 rapidly urbanizing regions such as on the North China Plain. The only study to date on
110 SAI impacts on PM_{2.5} pollution was a coarse resolution (4°×5°) global scale model with
111 sophisticated chemistry (Eastham et al., 2018). They simulated aerosol rainout from the
112 stratosphere to ground level, leading to an eventual increase in ground level PM_{2.5}.
113 Eastham et al. (2018) concluded that SAI changes in tropospheric and stratospheric
114 ozone dominated PM_{2.5} impacts on global mortality. However, this study did not
115 consider meteorological effects nor the situation in a highly polluted urban environment
116 such as included in our domain, and which is typical of much of the developing world.

117
118 The greater Beijing megalopolis lies in complex terrain, surrounded by hills and
119 mountains on three sides, and a flat plain to the southeast coast (Fig. 1). Over the period
120 1971-2014, apparent temperature rose at a rate of 0.42°C/10 years over Beijing-Tianjin-
121 Hebei region, with urbanization having an effect of 0.12°C/10 years (Luo and Lau,
122 2021). By the end of 2019, the permanent resident population in Beijing exceeded 21
123 million. Tianjin, 100 km from Beijing, is the fourth largest city in China with a
124 population of about 15 million, and Langfang (population 4 million) is about 50 km
125 from Beijing. Thus, the region contains a comparable urbanized population as the

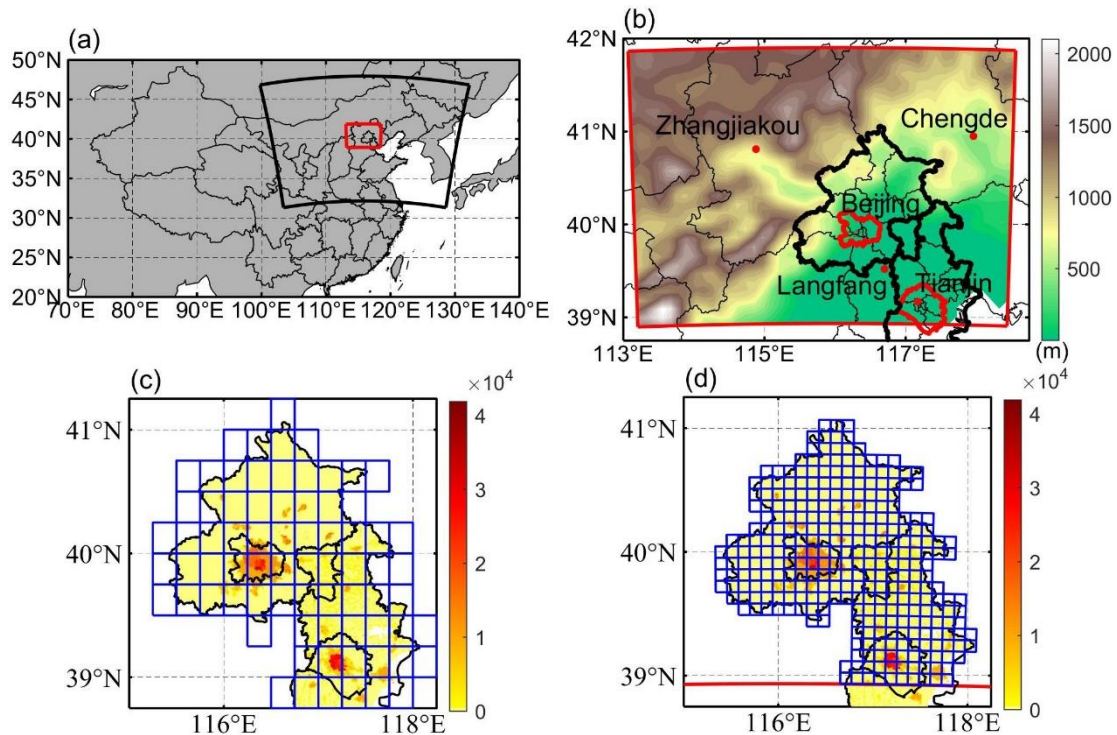

126 northeast US megalopolis. Since its climate is characterized by hot and moist summer
127 monsoon conditions, the population is at an enhanced risk as urban heat island effects
128 lead to city temperatures warming faster than their rural counterparts.

129

130 There are large uncertainties in projecting $PM_{2.5}$ concentration in the future due to both
131 climate and industrial policies. Statistical methods are much faster than atmospheric
132 chemistry models (Mishra et al., 2015), and different scenarios are easy to implement.
133 We use a Multiple Linear Regression (MLR) model to establish the links between $PM_{2.5}$
134 concentration, meteorology and emissions (Upadhyay et al., 2018; Tong et al., 2018).
135 We project and compare the differences of $PM_{2.5}$ concentration under G4 and RCP4.5
136 scenarios, and between different $PM_{2.5}$ emission scenarios. Accurate meteorological
137 data are crucial in simulating future apparent temperatures and $PM_{2.5}$ because all ESM
138 suffer from bias, and this problem is especially egregious at small scales. A companion
139 paper (Wang et al., 2022) looked at differences between downscaling methods with the
140 same 4 Earth System Models (ESM), domain and scenarios as we use here.

141

142 In this paper, we use the downscaled data to explore the effect of SAI on apparent
143 temperature and $PM_{2.5}$ over the greater Beijing megalopolis. The paper is organized as
144 follows. The data and methods of calculating AP, AP thresholds, the $PM_{2.5}$ MLR model
145 and its validation are briefly described in Section 2. The results from present day
146 simulation and future projections on apparent temperature and $PM_{2.5}$ are given in
147 Section 3, along with their associated impact analyses. In Section 4 we discuss and
148 interpret the findings, and finally we conclude with a summary of the main implications
149 of the geoengineering impacts on these two important human health indices in Section
150 5.

151

152 **Figure 1. a**, The 10 km WRF domain (red box) nested inside a 30 km resolution WRF domain (large

153 black sector). **b**, The inner domain topography and major conurbations (red dots), with the urban areas
154 of Beijing and Tianjin enclosed in red curves. Panels **c** and **d** show the population density (persons per
155 km²) of Beijing and Tianjin provinces (defined by black borders) in 2010 and the grid cells within the
156 Beijing-Tianjin province (blue boxes) when downscaled by ISIMIP (**c**) and WRF (**d**).

157 **2. Data and Methods**

158 **2.1 Scenarios, ESM, downscaling methods and bias correction**

159 The scenarios, ESM, downscaling methods and bias correction methods we use here
160 are as described in detail by Wang et al., (2022), and we just summarize the method
161 briefly here. We use three different scenarios: RCP4.5 and RCP8.5 (Riahi et al., 2011)
162 and the GeoMIP G4 scenario which span a useful range of climate scenarios: RCP4.5
163 is similar (Vandyck et al., 2016) to the expected trajectory of emissions under the 2015
164 Paris Climate Accord agreed Nationally Determined Contributions (NDCs); RCP8.5
165 represents a formerly business-as-usual, no climate mitigation policies, large signal to
166 noise ratio scenario; G4 represents a similar radiative forcing as produced by the 1991
167 Mount Pinatubo volcanic eruption repeating every 4 years.

168
169 Climate simulations are performed by 4 ESM: BNU-ESM (Ji et al., 2014), HadGEM2-
170 ES (Collins et al., 2011), MIROC-ESM (Watanabe et al., 2011) and MIROC-ESM-
171 CHEM (Watanabe et al., 2011). We compare dynamical and statistical downscaling
172 methods to convert the ESM data to scales more suited to capturing differences between
173 contrasting rural and urban environments. To validate the downscaled AP from model
174 results, we use the daily temperature, humidity and wind speed during 2008-2017 from
175 the gridded observational dataset CN05.1 with the resolution of 0.25°×0.25° based on
176 the observational data from more than 2400 surface meteorological stations in China,
177 which are interpolated using the “anomaly approach” (Wu and Gao, 2013). This dataset
178 is widely used, and has good performance relative to other reanalysis datasets over
179 China (Zhou et al., 2016; Yang et al., 2019; Yang et al., 2023; Yang and Tang, 2023).
180 Dynamical downscaling for the 4 ESM datasets was done with WRFv.3.9.1 with a
181 parameter set used for urban China studies (Wang et al., 2012) in two nested domains
182 at 30 and 10 km resolution over 2 time slices (2008-2017 and 2060-2069). We corrected
183 the biases in WRF output using the quantile delta mapping method (QDM; Wilcke et
184 al., 2013) with ERA5 (Hersbach et al., 2018) to preserve the mean probability density
185 function of the output over the domain without degrading the WRF spatial pattern. All
186 WRF results presented are after QDM bias correction. Statistical downscaling was done
187 with the trend-preserving statistical bias-correction Inter-Sectoral Impact Model
188 Intercomparison Project (ISIMIP) method (Hempel et al., 2013) for the raw ESM output,
189 producing output matching the mean ERA5 observational data in the reference
190 historical period with the same spatial resolution, while allowing the individual ESM
191 trends in each variable to be preserved.

192

193 **2.2 PM_{2.5} concentration and emission data**

194 In China there were few PM_{2.5} monitoring stations before 2013 (Xue et al., 2021).
 195 However, aerosol optical depths produced by the Moderate Resolution Imaging
 196 Spectroradiometer (MODIS) have been used to build a daily PM_{2.5} concentration
 197 dataset (ChinaHighPM2.5) at 1 km resolution from 2000 to 2018 (Wei et al., 2020). We
 198 use monthly PM_{2.5} concentration data during 2008-2015 from ChinaHighPM2.5 to train
 199 the MLR model, and the data during 2016-2017 to validate it. Figure S1 shows annual
 200 PM_{2.5} concentration over Beijing areas during 2008 (a) and 2017 (b).

201

202 Recent gridded monthly PM_{2.5} emission data were derived from the Hemispheric
 203 Transport of Air Pollution (HTAP_V3) with a resolution of 0.1°×0.1° during 2008-2017,
 204 which is a widely used anthropogenic emission dataset (Janssens-Maenhout et al.,
 205 2015). PM_{2.5} emissions over Beijing areas during 2008 (c) and 2017 (d) are shown in
 206 Fig. S1.

207

208 Future gridded monthly PM_{2.5} emissions to 2050 are available in the ECLIPSE V6b
 209 database (Stohl et al., 2015), generated by the GAINS (Greenhouse gas Air pollution
 210 Interactions and Synergies) model (Klimont et al., 2017). The ECLIPSE V6b baseline
 211 emission scenario assumes that future anthropogenic emissions are consistent with
 212 those under current environmental policies, hence it is the “worst” scenario without
 213 considering any mitigation measures (Li et al., 2018; Nguyen et al., 2020). Projected
 214 emissions are shown in Fig S2, with emissions plateauing at ~40 kt/year after 2030, so
 215 we assume 2060s levels are similar. These ECLIPSE projections are significantly larger
 216 than present day estimates from HTAP_V3. We therefore estimate 2060s emissions as
 217 the recent gridded monthly PM_{2.5} emissions from HTAP_V3 scaled by the ratios of
 218 2050 ECLIPSE emission to average annual emissions between 2010 and 2015. Before
 219 processing data, PM_{2.5} concentration is bilinearly interpolated to the WRF and ISIMIP
 220 grids, while PM_{2.5} emissions are conservatively interpolated to the target grids.

221

222 2.3 Apparent temperature

223 We use the formula proposed in Steadman (1984) to estimate apparent temperature
 224 under shade, which has been widely used to study heat waves, heat stress and
 225 temperature-related mortality (Perkins and Alexander, 2013; Lyon and Barnston, 2017;
 226 Lee and Sheridan, 2018; Zhu et al., 2021):

$$227 \quad AP = -2.7 + 1.04 \times T + 2 \times P - 0.65 \times W \quad (1)$$

228 where AP is the apparent temperature (°C) under shade meaning that radiation is not
 229 considered; T is the 2 m temperature (°C), W is the wind speed at 10 m above the ground
 230 (m/s), and P is the vapor pressure (kPa) calculated by

$$231 \quad P = P_s \times RH \quad (2)$$

232 where P_s is the saturation vapor pressure (kPa), and RH is the relative humidity (%).
 233 P_s is calculated using the Tetens empirical formula (Murray, 1966):

$$234 \quad P_s = \begin{cases} 0.61078 \times e^{\left(\frac{17.2693882 \times T}{T+237.3}\right)}, & T \geq 0 \\ 0.61078 \times e^{\left(\frac{21.8745584 \times (T-3)}{T+265.5}\right)}, & T < 0 \end{cases} \quad (3)$$

235 To assess the potential risks of heat-related exposure from apparent temperature, we
236 also count the number of days with $AP > 32^{\circ}\text{C}$ (NdAP_32) in the Beijing-Tianjin
237 province (Table S1). This threshold does not lead to extreme risk and death, instead it
238 is classified as requiring “extreme caution” by the US National Weather Service
239 (National Weather Service Weather Forecast Office,
240 <https://www.weather.gov/ama/heatindex>), but carries risks of heatstroke, cramps and
241 exhaustion. A threshold of 39°C is classed as “dangerous” and risks heatstroke. While
242 hotter AP thresholds would give a more direct estimate of health risks, the statistics of
243 these presently rare events mean that detecting differences between scenarios is less
244 reliable than using the cooler NdAP_32 threshold simply because the likelihood of rare
245 events are more difficult to accurately quantify than more common events that are
246 sampled more frequently. There is evidence that in some distributions, the likelihood
247 of extremes will increase more rapidly than central parts of a probability distribution,
248 for example large Atlantic hurricanes increasing faster than smaller ones (Grinsted et
249 al., 2013). But the conservative assumption is that similar differences between scenarios
250 would apply for higher thresholds as lower ones.

251 **2.4 Population Data Set**

252 Since health impacts are more important where there are more people, we calculate the
253 NdAP_32 weighted by population (Fig. 1c and 1d). We employ gridded population data
254 (Fu et al., 2014; <https://doi.org/10.3974/geodb.2014.01.06.V1>) with a spatial resolution
255 of 1×1 km collected in 2010. The population density distribution in Beijing and Tianjin
256 provinces with the ISIMIP and WRF grid cells contained are shown in the Fig. 1c and
257 1d.

258

259 **2.5 MLR model calibration**

260 Previous studies have shown that wind and humidity are the dominant meteorological
261 variables for $\text{PM}_{2.5}$ concentration in region we study (Chen et al., 2020). Hence, we
262 generate an MLR model between $\text{PM}_{2.5}$ and temperature (T), relative humidity (H),
263 zonal wind (U), meridional wind (V) and $\text{PM}_{2.5}$ emissions (E) at every grid cell as
264 follows:

265

$$266 \quad \text{PM}_{2.5} = \sum a_i X_i + b \quad (4)$$

267 Where $X_{i(i=1,2,3,4,5)}$ are the five factors, a_i are the regression coefficients of the X_i
268 with $\text{PM}_{2.5}$, and b is the intercept, which is a constant. We assume that all factors
269 should be included in the regression. All the meteorological variables are from the
270 statistical and dynamical downscaling and bias corrected results during 2008-2017,
271 with the first 8 years used for training model and the second 2 years used for validating
272 model. We train the MLR for the 4 ESMs under statistical and dynamical downscaling
273 in each grid cell separately, thus accounting spatial differences in the weighting of the
274 X_i across the domain. Meteorological variables under G4, RCP4.5 and RCP8.5 during
275 2060-2069 are used for projection.

276

277 The contributions of meteorology and PM_{2.5} emissions on future concentrations are
278 examined by using recent PM_{2.5} emissions (baseline) and future PM_{2.5} emissions
279 (mitigation), and the downscaled climate scenarios. Modeled PM_{2.5} concentration using
280 recent meteorology and PM_{2.5} emissions during 2008-2017 (2010s) is considered as our
281 reference.

282 2.6 MLR model validation

283

284 **Figure 2.** Scatter grams of PM_{2.5} concentration derived by MODIS and estimated by MLR during
285 validation period (2016-2017). Top figures (a-d) are the ISIMIP statistical downscaling results, and
286 bottom figures (e-h) are the WRF dynamical downscaling results. R² means the variance explained
287 by the MLR, and color bar denotes the density of datapoints at integer intervals.

288

289 Figure 2 shows the scattergram of PM_{2.5} concentration between ChinaHighPM2.5
290 dataset and MLR model during validation period based on ISIMIP and WRF results.
291 Observations and MLR models have Pearson's correlations coefficients around 0.86 for
292 ISIMIP results during the validation period, and the coefficient of determination of
293 MLRs are 0.74-0.75 (Fig. 2a-d). WRF Pearson's correlations are slightly lower, 0.82-
294 0.85, and explained variance ranges from 0.68-0.72 (Fig. 2e-h). These results are
295 similar as found by Jin et al. (2022). We also compare the spatial patterns of observed
296 and modeled PM_{2.5} in Fig. S3. Both ISIMIP and WRF results can simulate the
297 distribution characteristics of high concentration of PM_{2.5} in the southeast and low
298 concentration in the northwest.

299

300 2.7 Relative risks of mortality related to PM_{2.5}

301 We estimate the effects of PM_{2.5} on mortality by considering changes in the relative risk

302 (RR) of mortality related to PM_{2.5}. We lack data on mortality rates in the study domain
 303 without which we cannot estimate numbers of fatalities, just the average population-
 304 weighted RR. Burnett et al. (2014) established the integrated exposure-response
 305 functions we use. The RR is non-linear in concentration, that is an initially low PM_{2.5}
 306 region will suffer higher mortality and RR than an initially high PM_{2.5} region if PM_{2.5}
 307 is increased by the same amount. Ran et al. (2023) provide RR values for PM_{2.5}
 308 concentrations up to 200 µg/m³ that includes the 5 main major disease endpoints
 309 (Global Burden of Disease Collaborative Network, 2013) of PM_{2.5} related mortality:
 310 chronic obstructive pulmonary disease, ischemic heart disease, lung cancer, lung
 311 respiratory infection and stroke. We calculate the average population-weighted relative
 312 risks based on the gridded population dataset (Section 2.4) and PM_{2.5} concentration in
 313 the Beijing-Tianjin province defined in the Fig. 1c-1d, following Ran et al. (2023):

$$314 \quad RR_{pop,k} = \frac{\sum_{g=1}^G POP_g \times RR_k(C_g)}{\sum_{g=1}^G POP_g} \quad (5)$$

315 $RR_{pop,k}$ is the average population-weighted relative risk of disease k ($k=1-5$), POP_g is
 316 the population of grid g , and $RR_k(C_g)$ is the relative risk of disease k when PM_{2.5}
 317 concentration is C_g in the grid of g .

318

319 **2.8 Determination of contributions to change in AP and PM_{2.5}**

320 Equation (1) describes how AP is calculated, and this can be broken down into how
 321 much equivalent temperature is produced by each term (Fig. 3), with 2008-2017 as the
 322 baseline interval for season-by-season contributors to AP. Across scenario seasonal
 323 differences in contributors are then calculated as follows. We use an MLR approach,
 324 since this minimizes the square differences from the mean across the dataset, with the
 325 attendant assumption of independence between the data. Alternatives may also be
 326 considered that e.g. minimize the impact of outliers by considering the magnitude of
 327 the differences, but we prefer to keep the attractive properties of a least squares
 328 approach. The dependent variable in the MLR is the change in AP (ΔAP) and the
 329 independent variables are changes in each factor for each future scenario,

$$330 \quad \Delta AP = \sum \alpha_i X_i + \beta \quad (6)$$

331 where $X_{i(i=1,2,3)}$ are the daily changes of the three meteorological factors between two
 332 scenarios: 2 m temperature (ΔT), 2 m relative humidity (ΔRH) and 10 m wind speed
 333 (ΔW), α_i are the regression coefficients of the X_i with ΔAP , and β is the intercept,
 334 which is a constant. We assume that all three meteorological factors should be included
 335 in the regression and we estimate the contributions of each factor to changes of AP as:

$$336 \quad K_i = \frac{\alpha_i \bar{X}_i}{\sum \alpha_i \bar{X}_i} \quad (7)$$

337 where $K_{i(i=1,2,3)}$ is the contributions (in units of temperature) from each factor to the
 338 changes of the AP, and \bar{X}_i are the mean differences in temperature equivalent due to
 339 each factor between two scenarios.

340

341 The contribution of changes in each factor in changes of $PM_{2.5}$ is simpler since we
 342 assume that the relationship between each factor and $PM_{2.5}$ is linear, and so its
 343 contribution is the ratio of product of the regression coefficient and the change of each
 344 factor to the change of $PM_{2.5}$.
 345

346 3. Results

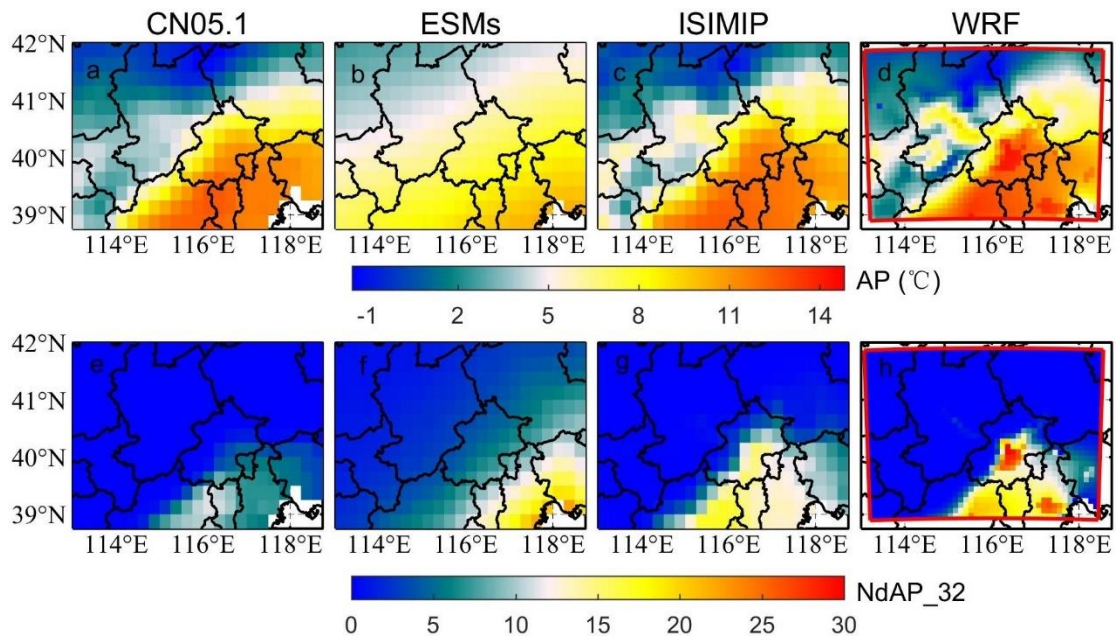

347 3.1 Recent apparent temperatures

348
 349 **Figure 3.** Seasonal averaged AP and equivalent temperature of each term in equation 1 for Beijing-
 350 Tianjin province (a-c) and Beijing-Tianjin urban areas (d-f) during 2008-2017 from CN05.1 (a, d), 4-
 351 model ensemble mean after ISIMIP (b, e) and ensemble mean after WRF (c, f). Term 1 is 1.04T, term 2
 352 is 2P and term 3 is -0.65W.
 353

354 Figure 3 shows the seasonal averaged AP and equivalent temperatures caused by
 355 temperature, relative humidity and wind speed in Beijing-Tianjin province and Beijing-
 356 Tianjin urban areas during 2008-2017. According to the CN05.1 results (Fig. 3a, 3d),
 357 AP and the separate 3 terms show similar seasonal patterns over the whole province
 358 and just the urban areas. Vapor pressure is higher in summer and wind speed is higher
 359 in spring. AP is lower than 2 m temperature in all seasons except summer, and especially
 360 lower in winter. AP, temperature, vapor pressure and wind speed are all higher in urban
 361 areas than in the surrounding rural region in any season. The ISIMIP results (Fig. 3b,
 362 3e), by design, perfectly reproduce the CN05.1 seasonal characteristics of AP,
 363 temperature, vapor pressure and wind speed. WRF shows a similar pattern with that
 364 from CN05.1, but for the Beijing-Tianjin province, WRF overestimates both 2 m
 365 temperature and AP in winter by 2.1°C and by 1.7°C respectively relative to CN05.1

366 (Fig. 3c). In the Beijing-Tianjin urban areas, WRF overestimates the temperature and
 367 AP relative to CN05.1 in all seasons, especially in winter (Fig. 3f).
 368

369
 370 **Figure 4.** Top row: the spatial distribution of mean apparent temperature from CN05.1 (a), raw ESMs
 371 ensemble mean after bilinear interpolation (b), 4-model ensemble mean after ISIMIP (c) and ensemble
 372 mean after WRF (d) during 2008-2017. Bottom row: the spatial distribution of annual mean number of
 373 days with AP > 32°C from CN05.1 (e), ESMs (f), ISIMIP (e) and WRF (f) during 2008-2017. Fig. S4
 374 and Fig. S5 show the pattern of AP and NdAP_32 for the individual ESM.

375 We compare the simulations of mean apparent temperature and NdAP_32 from both
 376 WRF dynamical downscaling with QDM and from ISIMIP statistical downscaling
 377 during 2008-2017 in Fig. 4. Both WRF with QDM and ISIMIP methods produce a
 378 pattern of apparent temperature which is close to that from CN05.1. While the raw AP
 379 from ESMs is overestimated in Zhangjiakou high mountains and underestimated in the
 380 southern plain, and shares a similar pattern with temperature from ESMs (Wang et al.,
 381 2022). The raw ESM outputs were improved after dynamical and statistical
 382 downscaling. The average annual AP from ISIMIP (9.6-9.7°C) is 0.5°C higher than that
 383 from CN05.1 (9.1°C) over the Beijing-Tianjin province for all ESMs (Table 1). While
 384 WRF produces warmer apparent temperatures in the city centers of Beijing and Tianjin
 385 and lower ones in the high Zhangjiakou mountains than recorded in the lower resolution
 386 CN05.1 observations. There are also differences between different models after WRF
 387 downscaling. For example, apparent temperatures from the two MIROC models
 388 downscaled by WRF are the warmest. In contrast AP from all 4 ESMs after ISIMIP
 389 shows very similar patterns (Fig. S4).

390
 391 ESMs tend to overestimate the number of days with AP > 32°C in southeastern Beijing
 392 and the whole Tianjin province. Both ISIMIP and WRF appear to overestimate the
 393 NdAP_32 in Beijing urban areas and the southerly lowland areas although NdAP_32 is
 394 close to zero in the colder rural areas at relatively high altitude for both downscaling

395 methods. Some of these differences may be due to the WRF simulations being at finer
 396 resolution than the $0.25^{\circ} \times 0.25^{\circ}$ CN05.1, leading to higher probabilities of high AP in
 397 urban areas (Fig. 5d). ISIMIP results also show slight overestimations, especially in the
 398 tails of the distribution ($AP > 30^{\circ}C$) for urban areas (Fig. 5c). CN05.1 gives about 5
 399 NdAP_32 per year in southern Beijing and Tianjin, but there are nearly 15 NdAP_32
 400 from ISIMIP, and over 20 NdAP_32 per year from WRF downscaling in the Beijing-
 401 Tianjin urban areas during 2008-2017. NdAP_32 from WRF and ISIMIP downscaling
 402 of all ESM is overestimated relative to CN05.1. But there are differences in ESM under
 403 the two downscalings: with ISIMIP, HadGEM2-ES and BNU-ESM have more
 404 NdAP_32 than the two MIROC models, while the reverse occurs with WRF (Fig. S5).
 405

406 **Table 1.** The annual mean apparent temperature and population weighted NdAP_32 in Beijing-Tianjin
 407 province and Beijing-Tianjin urban areas (Fig. 1b) from CN05.1, ISIMIP and WRF during 2008-2017.

Data Sources	AP ($^{\circ}C$)				NdAP_32 (day yr $^{-1}$)	
	Provinces		Urban		Population weighted for province (Fig. 1c, 1d)	
	WRF	ISIMIP	WRF	ISIMIP	WRF	ISIMIP
MIROC-ESM	10.5	9.6	13.6	11.4	22.2	10.1
MIROC-ESM-CHEM	10.5	9.6	13.6	11.4	21.9	11.0
HadGEM2-ES	9.5	9.6	12.0	11.4	12.3	11.1
BNU-ESM	9.4	9.7	11.8	11.5	10.2	12.7
CN05.1	9.1		11.1		2.4	

408 The Taylor diagram of the daily mean apparent temperature in Beijing-Tianjin province
 409 and Beijing-Tianjin urban areas from 2008-2017 for the 4 ESMs shows that correlation
 410 coefficients between ESMs and CN05.1 are greater than 0.85 under both downscaling
 411 methods. Although there are differences between ESMs, the performance of WRF, with
 412 higher correlation coefficient and smaller SD (standard deviation) and RMSD (root
 413 mean standard deviation), is usually superior to ISIMIP (Fig. S6). Taking the Beijing-
 414 Tianjin urban areas as an example (Fig. S6b), under the ISIMIP method, MIROC-ESM,
 415 MIROC-ESM-CHEM and HadGEM2-ES have the same correlation coefficient (0.92)
 416 and RMSD ($5.4^{\circ}C$) with the CN05.1, while BNU-ESM has lower correlation coefficient
 417 (0.88) and higher RMSD ($7.0^{\circ}C$). Under WRF simulations, MIROC-ESM and MIROC-
 418 ESM-CHEM have larger correlation coefficients and smaller RMSD with CN05.1 than
 419 HadGEM2-ES and BNU-ESM.

420 Figure 5 shows the probability density functions (pdf) of daily AP from the four ESMs
 421 under ISIMIP and WRF in Beijing-Tianjin province and Beijing-Tianjin urban areas
 422 during 2008-2017. ISIMIP overestimates the probability of extreme cold AP relative to
 423 CN05.1 (especially BNU-ESM), although all ESM reproduce the CN05.1 pdf well at
 424 high AP. WRF can reproduce the CN05.1 distribution of AP better than ISIMIP, but
 425 high AP is overestimated relative to CN05.1 and the urban areas perform less well than
 426 the whole Beijing-Tianjin province. In urban areas all ESMs driving WRF tend to
 427 underestimate the probability of lower AP and to overestimate the probability of higher
 428 AP, especially the two MIROC models (Fig. 5d). Fig. S7 displays the annual cycle of
 429 monthly AP, with ISIMIP proving excellent by design, at reproducing the monthly AP.

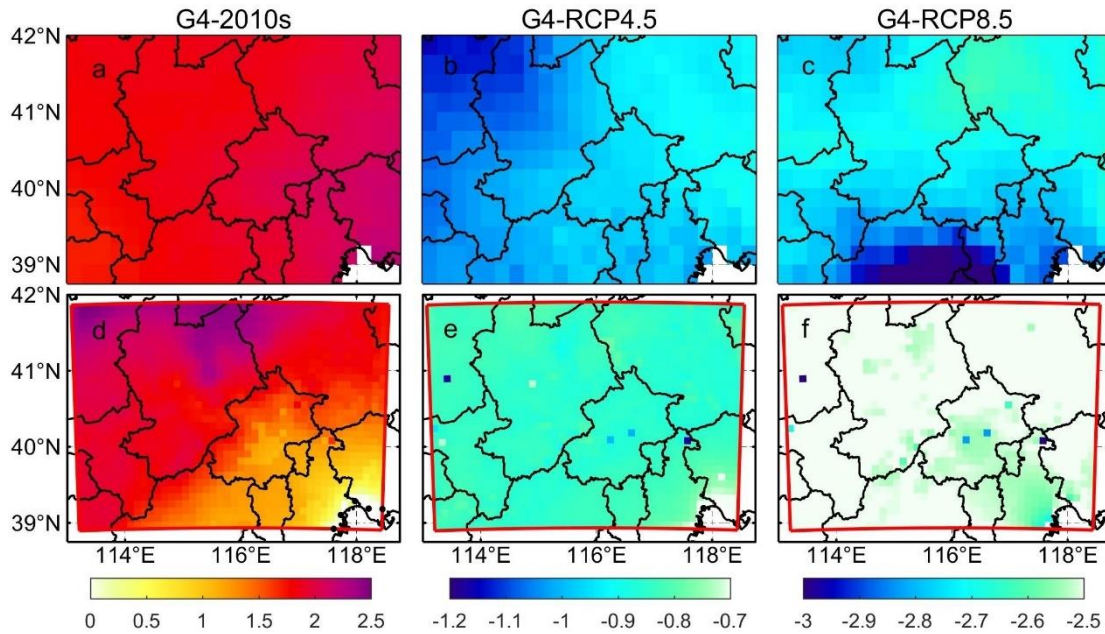

430 While under WRF downscaling AP shows more across model differences, especially
431 during summer and with greater spread for the urban areas.

432
433 **Figure 5.** The probability density function (pdf) for daily apparent temperature under ISIMIP (a, c) and
434 WRF (b, d) results in Beijing-Tianjin province (a, b) and Beijing-Tianjin urban areas (c, d) during 2008-
435 2017.

436 3.2 2060s apparent temperatures

437 3.2.1 Changes of apparent temperature

438

439 **Figure 6.** Spatial pattern of ensemble mean apparent temperature difference ($^{\circ}\text{C}$) under different
 440 scenarios over 2060-2069: G4-2010s (left column), G4-RCP4.5 (middle column) and G4-RCP8.5 (right
 441 column) based on ISIMIP and WRF methods. 2010s refers to the 2008-2017 period. Stippling indicates
 442 grid points where differences or changes are not significant at the 5% level according to the Wilcoxon
 443 signed rank test.
 444

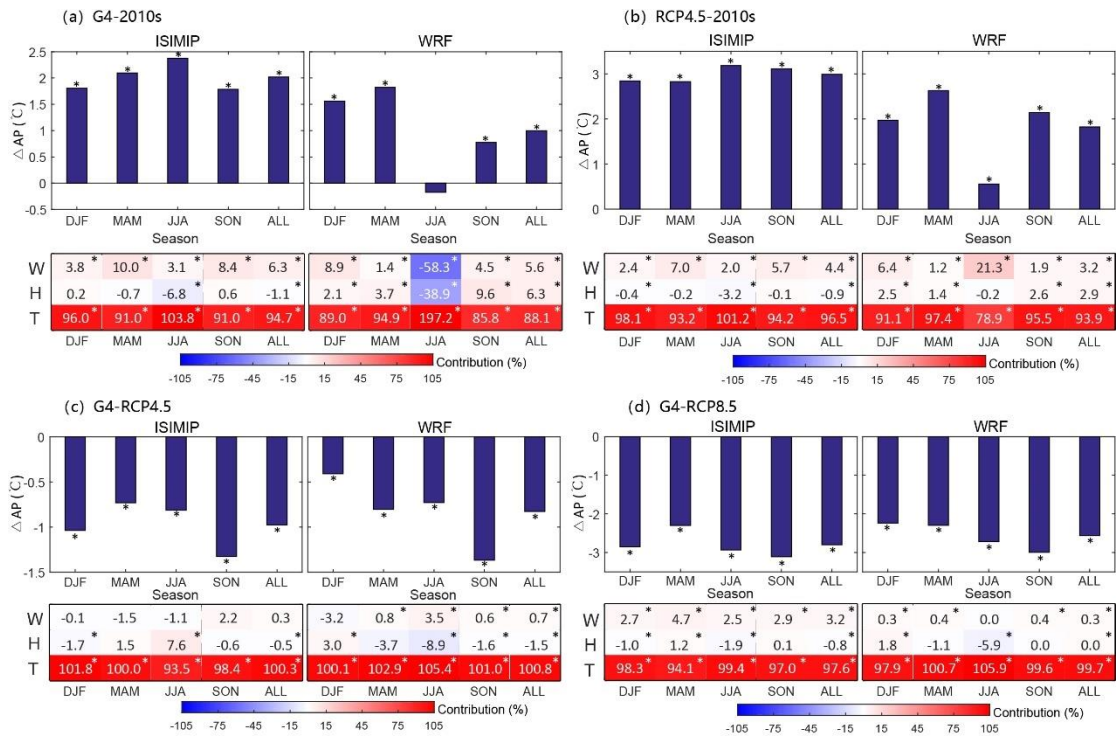

445 Figure 6 shows the ISIMIP and WRF ensemble mean changes in the annual mean AP
 446 under G4 during 2060-2069 relative to the past and the two future RCP scenarios.
 447 ISIMIP-downscaled AP (Fig. 6a-6c) shows significant anomalies ($p < 0.05$), with whole
 448 domain rises of 2.0°C in G4-2010s, and falls of 1.0°C and 2.8°C in G4-RCP4.5 and
 449 G4-RCP8.5 respectively. In WRF results, AP under G4 is about $1\text{-}2^{\circ}\text{C}$ warmer than
 450 that under 2010s, 0.8°C and 2.5°C colder than that under RCP4.5 and RCP8.5 over
 451 the whole domain. Individual ESM results downscaled by ISIMIP and WRF are in Fig.
 452 S9 and Fig. S10. For both ISIMIP and WRF downscaling results, the two MIROC
 453 models show stronger warming than the other two models between G4 and the 2010s.
 454 WRF-downscaled AP driven by HadGEM2-ES exhibits the strongest cooling, with
 455 decreases of 1.7°C between G4 and RCP4.5 and falls of 3.0°C between G4 and RCP8.5.
 456 Although different ESMs show different changes in AP between G4 and other scenarios,
 457 changes in AP are almost the same everywhere for a given ESM in the ISIMIP results
 458 (Fig. S9). WRF-downscaled AP anomalies driven by two MIROC models are larger in
 459 the Zhangjiakou mountains and smaller in the Beijing urban areas and Tianjin city
 460 between G4 and 2010s (Fig. S10). Changes in AP from ISIMIP results, whether across
 461 whole province or just the urban areas, are statistically identical given scenarios (Table
 462 2), which is consistent with patterns in figure 6. AP under G4 is 0.8°C (1.0°C) and
 463 2.6°C (2.8°C) colder than that under RCP4.5 and RCP8.5 in Beijing-Tianjin urban
 464 areas from ISIMIP (WRF) results. The warming between G4 and 2010s in urban areas
 465 is 1.0°C in WRF results, while that is 2.0°C in ISIMIP results (Table 2).
 466

467 **Table 2.** Difference of apparent temperature between the G4 and other scenarios for the Beijing-Tianjin
 468 province and Beijing-Tianjin urban areas as defined in Fig. 1b during 2060-2069. Bold indicates the
 469 differences or changes are significant at the 5% level according to the Wilcoxon signed rank test.
 470 (Units: °C)

Model	G4-2010s				G4-RCP4.5				G4-RCP8.5

471

472 3.2.2 Contributing factors to changes in AP

473

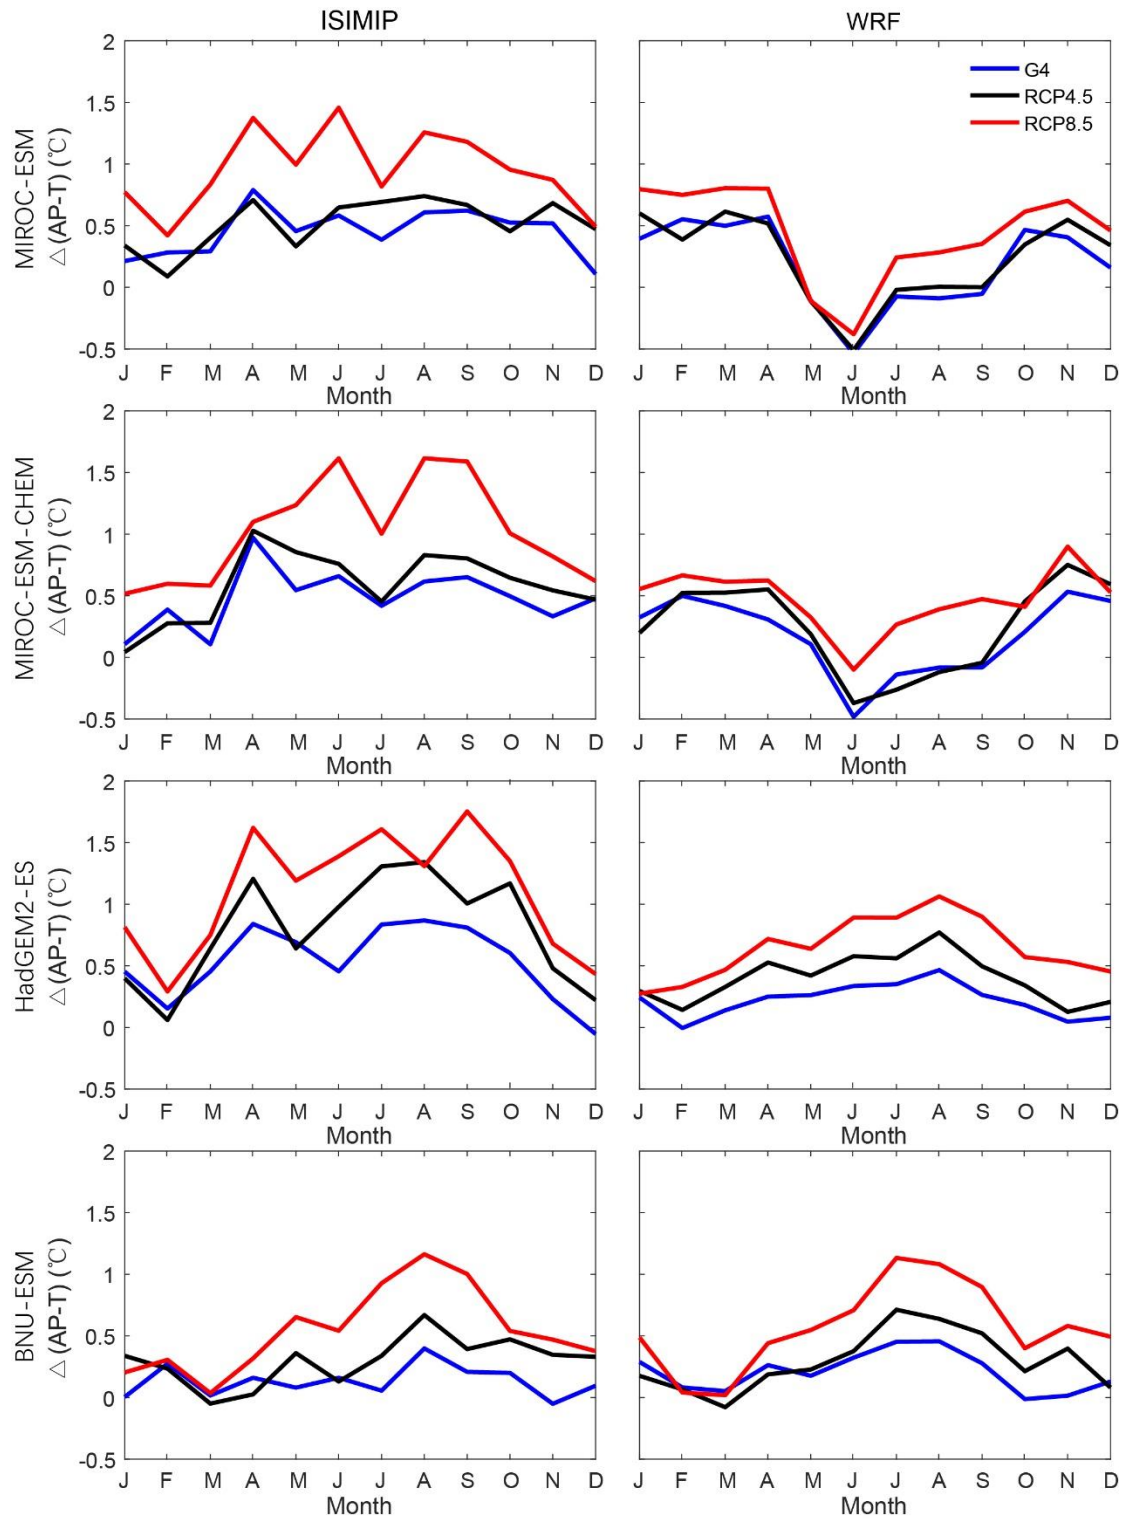

474 **Figure 7.** The seasonal changes of AP (ΔAP) and the seasonal contribution of climatic factors to ΔAP
 475 for Beijing and Tianjin urban areas under ISIMIP and WRF between G4 and 2010s (a), G4 and 2010s
 476 (b), G4 and RCP4.5 (c) and G4 and RCP8.5 (d) in the 2060s based on ensemble mean results. Colors
 477 and numbers in each cell correspond to color bar, and “*” above the columns and in the cells indicate
 478 differences are significant at the 5% significant level under the Wilcoxon test.

479

480 Figure 7 shows the ISIMIP and WRF ensemble mean changes in the annual mean AP
 481 anomalies G4 during 2060-2069 relative to the past and the two future RCP scenarios.
 482 ISIMIP-downscaled AP (Fig. 7a-7c) shows significant anomalies ($p < 0.05$) across the
 483 whole domain, even for the relatively small differences in G4-RCP4.5. ΔAP by WRF
 484 is lower than that by ISIMIP. Between G4 and 2010s, AP are projected to have increases

485 of 1.8 (1.6), 2.1 (1.8), 2.4 (-0.2), 1.8 (0.8) °C from winter to autumn in ISIMIP (WRF)
486 results. In ISIMIP results, the contribution of temperature ranges from 91%-104%, and
487 the contribution of wind speed ranges from 3%-10% in all seasons, while the
488 contribution of humidity is negative or insignificant (Fig. 7a). However, the
489 contribution of humidity is positive in WRF results (Fig. 7a). Between RCP4.5 and
490 2010s, annual mean AP is projected to increase by 3.0 °C and 1.8 °C in ISIMIP and
491 WRF results respectively, which is higher than that between G4 and 2010s. The increase
492 of temperature and decrease of wind speed have a significant impact on the annual
493 average Δ AP contributed 97% (94%) and 4% (3%) in ISIMIP (WRF) results. The
494 contributions of changes in humidity are significantly positive under G4 and RCP4.5 in
495 WRF results, while it is the opposite in the ISIMIP results (Fig. 7a-7b).

496
497 Relative to RCP4.5 in the 2060s, AP is projected to decrease by 1.0 (0.4), 0.7 (0.8), 0.8
498 (0.7), and 1.3 (1.4) °C from winter to autumn under G4 in ISIMIP (WRF) results (Fig.
499 7c). In summer, the contribution from changes in temperature and humidity are 94%
500 (105%) and 8% (-9%) in ISIMIP (WRF) results, respectively. There are insignificant
501 contributions from wind speed under ISIMIP results, but a significant slight positive
502 contribution (0.7%-4%) under WRF results (Fig. 7c). The annual mean AP under G4 is
503 2.8 (2.6) °C lower than that under RCP8.5 in ISIMIP (WRF) result. In this case, the
504 contribution of changes in wind on Δ AP ranges from 3%-5% by ISIMIP, while it is
505 close to 0 by WRF. As expected, Δ AP is mainly determined by the changes in
506 temperature, with contributions usually above 90% between different scenarios.

507

508 **Figure 8.** The change of apparent temperature based on air temperature under three scenarios (G4,
 509 RCP4.5 and RCP8.5) in four ESMs under ISIMIP (left column) and WRF (right column) for urban areas
 510 relative to the 2010s.

511

512 A useful measure of heat impacts that may be missed if considering only at air
 513 temperatures is the seasonality of the differences between AP and air temperature
 514 ($\Delta(AP-T)$; Fig. 8). The four model ensemble annual mean $\Delta(AP-T)$ under ISIMIP is

515 projected to rise by 0.4°C, 0.5°C and 0.9°C under G4, RCP4.5 and RCP8.5, relative to
 516 the 2010s. Under WRF, $\Delta(\text{AP-T})$ is much smaller than under ISIMIP but still rising
 517 faster than air temperatures: by 0.2°C, 0.3°C and 0.5°C under G4, RCP4.5 and RCP8.5
 518 relative to the 2010s, respectively. In general, the largest anomalies in $\Delta(\text{AP-T})$ are in
 519 summer under both WRF and ISIMIP downscaling, but the two MIROC models under
 520 WRF have small or even negative $\Delta(\text{AP-T})$ in summer with WRF.

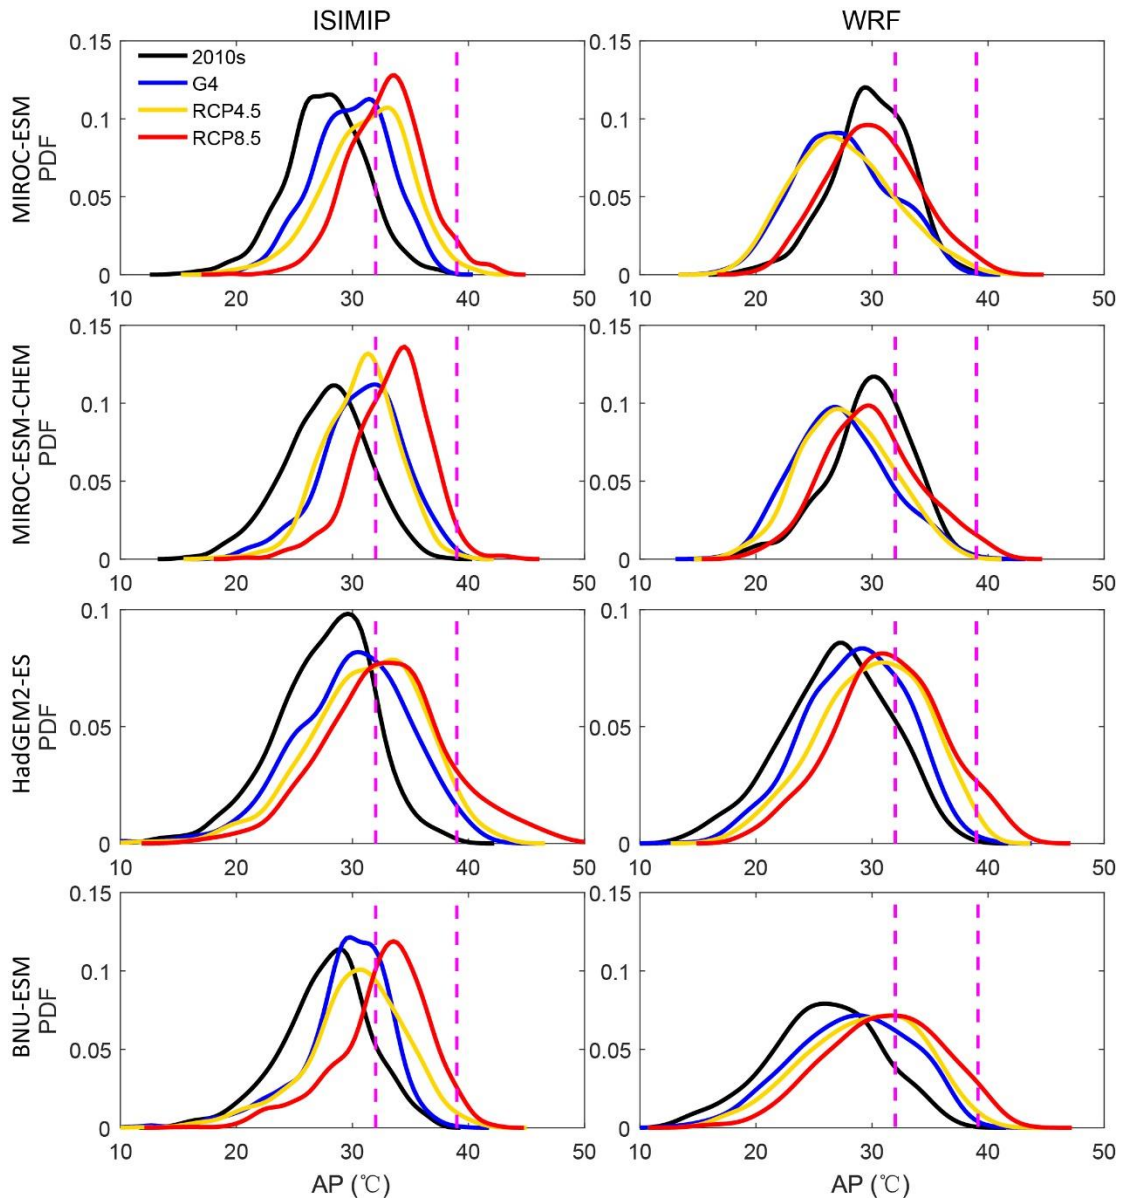

521 3.2.3 Changes of the number of days with $\text{AP} > 32^\circ\text{C}$

522 **Figure 9.** Ensemble mean differences in annual number of days with $\text{AP} > 32^\circ\text{C}$ (NdAP_{32}) between
 523 scenarios for 2060-2069: G4-2010s (left column), G4-RCP4.5 (second column) and G4-RCP8.5 (right
 524 column) based on ISIMIP method and WRF. 2010s means the results simulated during 2008-2017.
 525 Stippling indicates grid points where differences or changes are not significant at the 5% level according
 526 to the Wilcoxon signed rank test. Corresponding ISIMIP results for each ESM are in Fig. S11, and WRF
 527 results in Fig. S12.
 528

529
 530 The NdAP_{32} anomalies in Figure 9 show that ISIMIP projects an increase of about 20
 531 days per year with $\text{AP} > 32^\circ\text{C}$ for the southeast of Beijing province and 10 days in the
 532 western areas of Beijing under G4 relative to the 2010s. NdAP_{32} is about 10 days
 533 fewer under G4 than RCP4.5 with no clear spatial differences. G4 has about 35 fewer
 534 NdAP_{32} days in the southern part of the domain and 20 fewer days in the western
 535 domain than the RCP8.5 scenario. In contrast WRF suggests that most areas do not
 536 show any significant difference between G4 and the 2010s, while the anomalies relative
 537 to RCP4.5 are similar as ISIMIP, the differences are insignificant over more area than
 538 ISIMIP. G4-RCP8.5 anomalies with WRF are smaller than with ISIMIP, and differences
 539 are not significant in the Zhangjiakou high mountains. The urban areas show larger
 540 decreases in NdAP_{32} than the more rural areas, even in the low altitude plain.
 541 Individual ESM show almost no statistically significant differences between G4 and
 542 RCP4.5 (Fig. S11 and S12), but the differences seen in Fig. 9 are significant because of
 543 the larger sample size in the significance test. All ESMs with ISIMIP show more
 544 NdAP_{32} in the urban areas under G4 than the 2010s, while two MIROC models

545 driving WRF show fewer NdAP_32 in Beijing-Tianjin urban areas (Fig. S11, S12).
 546

547
 548 **Figure 10.** Probability density distributions of daily apparent temperature (AP) in summer (JJA) over
 549 Beijing-Tianjin urban areas under recent period (2008-2017), and the 2060s under G4, RCP4.5 and
 550 RCP8.5 scenarios from ISIMIP and WRF results. The purple dotted lines are at AP of 32°C and 39°C.

551
 552 The pdf of daily apparent temperature in summer over Beijing-Tianjin urban areas (Fig.
 553 10) shifts rightwards for G4, RCP4.5 and RCP8.5 during the 2060s relative to the 2010s.
 554 Figure 10 shows that by the 2060s, the dangerous threshold of AP>39 is crossed
 555 frequently under RCP8.5 with both WRF and ISIMIP downscaling, but for the RCP4.5
 556 and G4 scenarios these events are much rarer. ISIMIP results tend to show higher
 557 probability tails (extreme events) than under WRF simulations.

558
 559 Population weighted NdAP_32 in the 2060s for Beijing-Tianjin province is shown in
 560 Table 3. ISIMIP downscaling suggests ensemble mean rises in NdAP_32 of 22.4 days

561 per year under G4 relative to the 2010s, but that G4 has 8.6 and 33.5 days per year
 562 fewer than RCP4.5 and RCP8.5, respectively. NdAP₃₂ from WRF under G4 is
 563 reduced by 19.6 days per year relative to RCP8.5, and by 6.3 days relative to RCP4.5
 564 (Table 3).

565

566 **Table 3.** Difference of population weighted NdAP₃₂ between the G4 and other scenarios for Beijing-
 567 Tianjin province (Fig. 1c, 1d) during 2060-2069. Bold indicates the changes are significant at the 5%
 568 level according to the Wilcoxon signed rank test. (Units: day y⁻¹).

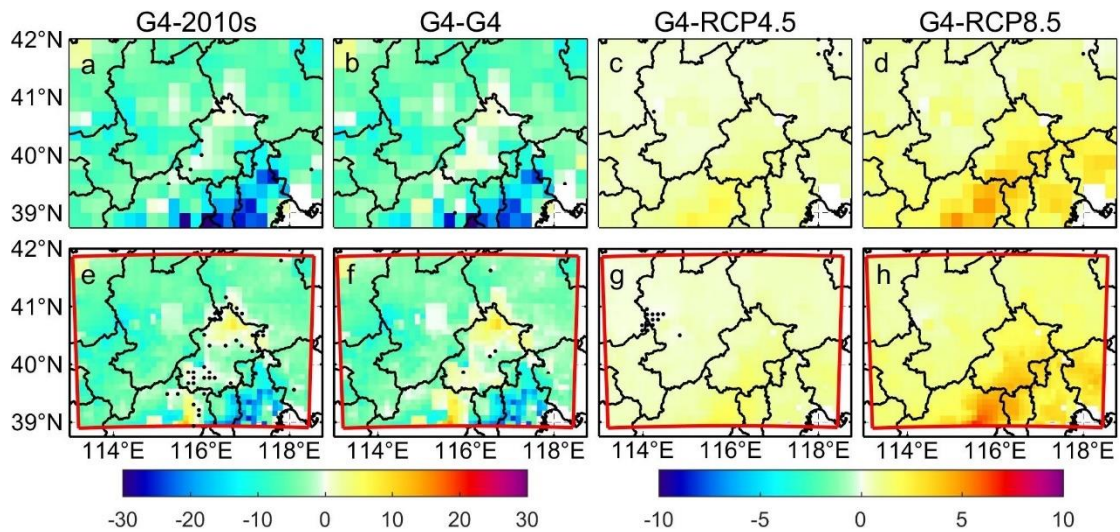

569

	Beijing-Tianjin province		G4-2010s		G4-RCP4.5		G4-RCP8.5

570

571 3.3 PM_{2.5} in the 2060s

572 3.3.1 PM_{2.5} scenarios in the 2060s

573

574 **Figure 11.** Spatial patterns of ensemble mean PM_{2.5} concentration difference (µg/m³) between
 575 “mitigation” under G4 in the 2060s and reference (**a, e**), between “mitigation” and “baseline” under
 576 G4 in the 2060s (**b, f**), between G4 and RCP4.5 under “mitigation” scenario in the 2060s (**c, g**), and
 577 between G4 and RCP8.5 under “mitigation” scenario in the 2060s (**d, h**) based on ISIMIP (**a-d**) and
 578 WRF (**e-h**) results. Stippling indicates grid points where differences or changes are not significant
 579 at the 5% significant level according to the Wilcoxon signed rank test.

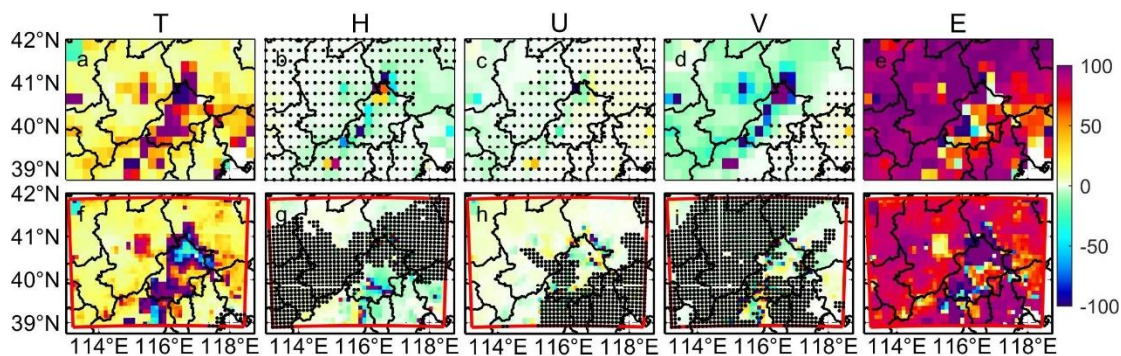

580

581 We firstly project the change of PM_{2.5} under G4 and the aerosol mitigation scenario in
 582 2060s relative to 2010s (Fig. 11a, e). Both ISIMIP and WRF project PM_{2.5} decreases in

583 most areas, especially in Tianjin and Langfang, but $PM_{2.5}$ decreases more under ISIMIP
 584 than WRF. $PM_{2.5}$ concentration decreases by $6.5 \mu\text{g}/\text{m}^3$ over Beijing-Tianjin province
 585 in ISIMIP, and decrease by $4.3 \mu\text{g}/\text{m}^3$ in WRF (Table S2). $PM_{2.5}$ concentration is $0.5\text{-}8$
 586 $\mu\text{g}/\text{m}^3$ higher in northern Beijing under G4 (“mitigation”) than that during the 2010s in
 587 WRF. To show the impact of emission reductions, we compare the $PM_{2.5}$ concentration
 588 between aerosol “baseline” and “mitigation” scenarios under G4 in the 2060s (Fig. 11b,
 589 11f), and compare the “mitigation” $PM_{2.5}$ concentration under G4 and the RCP
 590 scenarios in the 2060s to clarify the effect of geoengineering compared with climate
 591 warming. Compared with “baseline” scenario, $PM_{2.5}$ concentration is less under
 592 “mitigation” scenario as expected in both ISIMIP and WRF under G4 (Fig. 11b, 11f),
 593 and has a similar spatial pattern with that in Fig. 11a and 11e. Compared with RCP4.5
 594 and RCP8.5, $PM_{2.5}$ concentration under G4 are higher in ISIMIP results (Fig. 11c-11d),
 595 but with large differences between the 4 ESMS. G4 $PM_{2.5}$ is simulated greater than in
 596 RCP scenarios under HadGEM2-ES and BNU-ESM (Fig. S13k, l, o, p), but there are
 597 insignificant differences in most areas under the two MIROC models (Fig. S13c, d, g,
 598 h). $PM_{2.5}$ concentrations are larger between G4 and RCP8.5. WRF simulations shows
 599 similar changes in $PM_{2.5}$ between G4 and RCPs as ISIMIP (Fig. 11g-h).

600

601 3.3.2 $PM_{2.5}$ meteorological and emissions controls in the 2060s

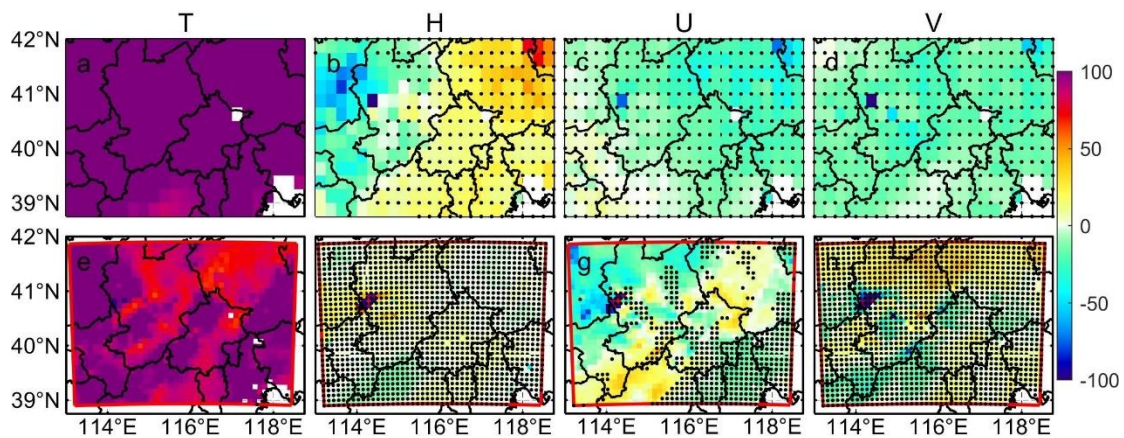

602

603 **Figure 12.** Contribution of climate factors (temperature/T, humidity/H, zonal wind/U, meridional
 604 wind/V) and emission (E) to changes in monthly $PM_{2.5}$ concentration ($\Delta PM_{2.5}$) in 2060s under G4
 605 (“mitigation”) relative to 2010s. Top figures (a-e) are ISIMIP results, and bottom figures (f-j) are
 606 WRF results. Stippling indicates the changes are insignificant at the 5% significant level in the
 607 Wilcoxon test.

608

609 Next, we quantify the contribution of different meteorological factors and $PM_{2.5}$
 610 emissions to $\Delta PM_{2.5}$ between G4 (“mitigation”) in the 2060s and the 2010s (Fig. 12).
 611 Both ISIMIP and WRF results show that the increase of temperature and decrease of
 612 $PM_{2.5}$ emission play positive roles in reducing $PM_{2.5}$ concentration. ISIMIP results (Fig.
 613 12a-e), suggest that the projected increase of temperature could explain 0-20% of the
 614 decrease of $PM_{2.5}$ concentration, and decrease of $PM_{2.5}$ emission could explain more
 615 than 90% of changes in $PM_{2.5}$ concentration differences in most of areas. Changes in

616 humidity and westerly winds (positive U-wind) do not cause significant changes in
 617 $\Delta PM_{2.5}$, but projected increases southerly wind (positive V-wind) is detrimental to the
 618 decrease in $PM_{2.5}$ concentration, and has a 0-10% negative effect on $\Delta PM_{2.5}$ in
 619 Zhangjiakou. WRF results show similar spatial pattern in effect of temperature and
 620 emission on $\Delta PM_{2.5}$ with ISIMIP results. Although temperature is projected to increase
 621 over the whole domain (Fig. S16), there are negative contributions on $\Delta PM_{2.5}$ to the
 622 north of Beijing due to increase of $PM_{2.5}$ caused by the negative correlation between
 623 $PM_{2.5}$ and its emissions (Fig. S20). The ~ 1 -2% wetter humidity has $\sim 10\%$ negative
 624 effect on decrease of $PM_{2.5}$ south of Beijing (Fig. 12g), and 0.2-0.3 m/s decreases of U-
 625 wind have 0-10% negative contribution on decrease of $PM_{2.5}$ in Zhangjiakou (Fig. 12h).
 626 The changes in each factor in ISIMIP and WRF results are shown in Fig. S15 and Fig.
 627 S16, respectively.

628
 629 **Figure 13.** Contribution of climate factors (as in Fig. 12) to changes in monthly $PM_{2.5}$ concentration
 630 in 2060s under G4 with aerosol “mitigation” relative to 2060s under RCP4.5 with aerosol
 631 “mitigation”. Top figures (a-e) are ISIMIP results, and bottom figures (f-j) are WRF results.
 632 Stippling indicates the changes are insignificant at the 5% significant level in the Wilcoxon test.

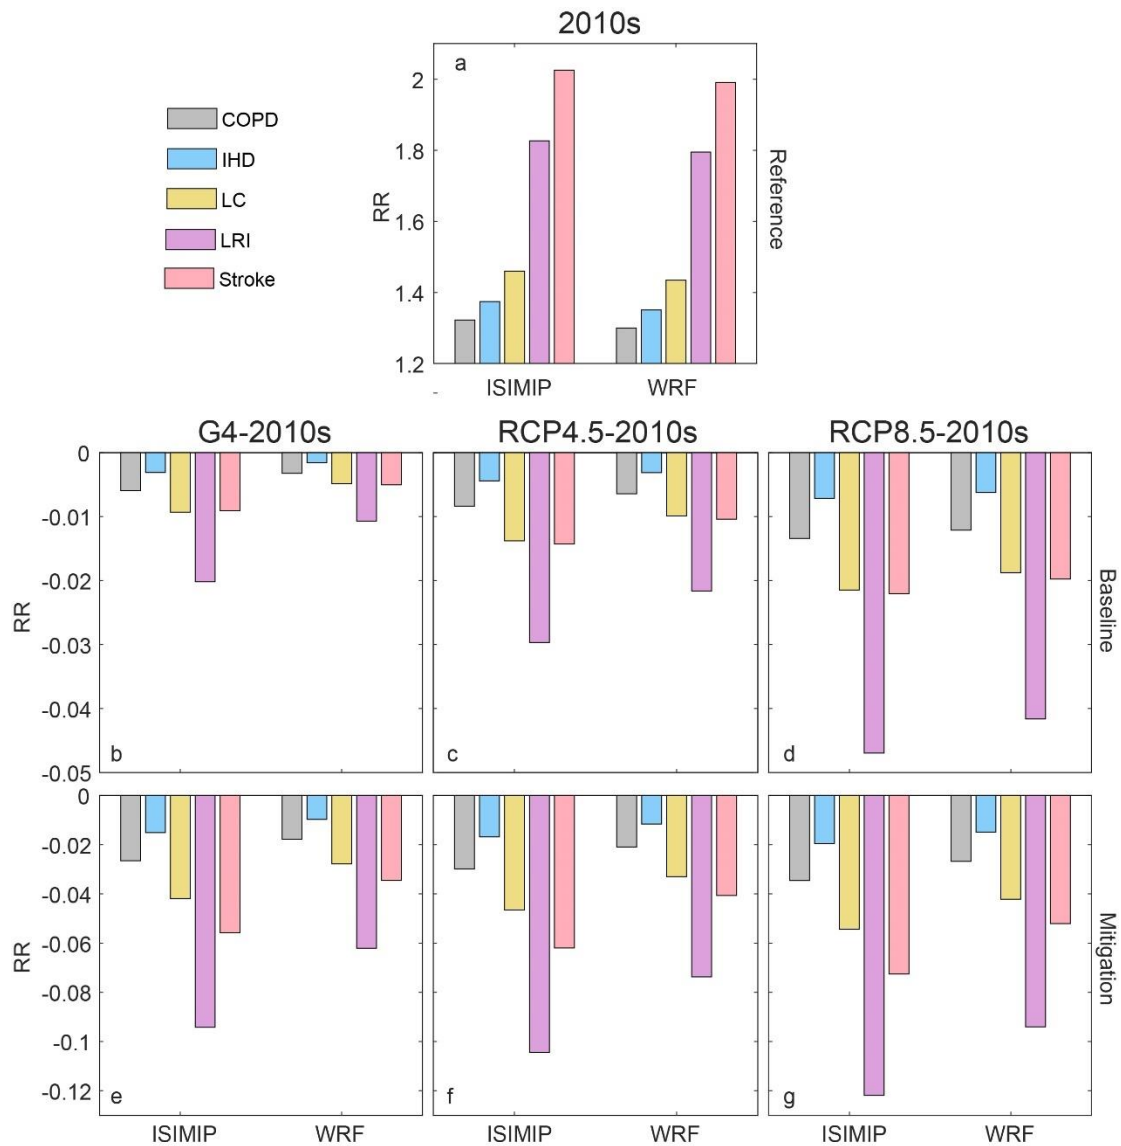

633

634 Now we explore the contribution of each meteorological factor to $\Delta PM_{2.5}$ between G4
 635 (“mitigation”) and RCP4.5 (“mitigation”) in the 2060s (Fig. 13). The higher $PM_{2.5}$
 636 under G4 is mainly caused by the lower temperature. In ISIMIP, lower temperature
 637 explains more than 90% (100% in some places) of the raised $PM_{2.5}$ relative to RCP4.5,
 638 although the increase of humidity is also helpful to lower $PM_{2.5}$ in the western domain
 639 (Fig. 13a-b). Humidity can increase suspended particle mass and coagulation,
 640 promoting deposition (Li et al., 2015). The contribution of differences in U-wind and
 641 V-wind on $\Delta PM_{2.5}$ is insignificant (Fig. 13c-d). In WRF, the projected lower
 642 temperatures explain more than 70% of the higher $PM_{2.5}$ under G4 relative to RCP4.5
 643 (Fig. 13e). Although the increase of southerly (V) wind contributes 10-20% to the
 644 higher $PM_{2.5}$ in the northern domain under HadGEM2-ES and BNU-ESM (Fig. S18),
 645 it is insignificant in the ensemble (Fig. 13h). Decreased westerlies (U wind) explains
 646 about between +20% and -20% of $PM_{2.5}$ differences (Fig. 13g), since U-wind impacts
 647 vary spatially (Fig. S20).

648

649 **3.3.3 PM_{2.5} impact on health risks now and in the 2060s**

650 Changes in RR of PM_{2.5} for the 5 diseases under the geoengineering and global
651 warming climate scenarios and different emission scenarios during 2060s relative to
652 2010s for the Beijing-Tianjin province are shown in Fig. 14. Present-day PM_{2.5} related
653 RRs are 1.32 (1.30), 1.37 (1.35), 1.46 (1.43), 1.83 (1.80) and 2.02 (1.99) for chronic
654 obstructive pulmonary disease (COPD), ischemic heart disease (IHD), lung cancer (LC),
655 lung respiratory infection (LRI) and stroke according to the ISIMIP (WRF) simulations
656 (Fig. 14a). RR of LRI is the highest and COPD is the lowest in the five diseases, and
657 WRF estimates of RR are 0.2-0.3 lower than those of ISIMIP. In both the “baseline”
658 and “mitigation” emission scenarios, RRs will be lower under G4, RCP4.5 and RCP8.5
659 compared with the 2010s. Smaller RR reductions occur under G4 than under RCP4.5
660 and RCP8.5, and ISIMIP simulates larger reductions than WRF. This is because the
661 PM_{2.5} concentrations from ISIMIP are reduced more than with WRF (Table S2). Under
662 the “baseline” emission scenario (Fig. 14b-d), the biggest reduction of RR for LRI is
663 0.047 under RCP8.5 in ISIMIP, and RRs for other diseases are projected to reduce by
664 no more than 0.02. Under the “mitigation” emission scenario (Fig. 14e-g), reductions
665 in RRs are 3-6 times greater.

666

667 **Figure 14.** Average population-weighted relative risks of PM_{2.5} related 5 diseases in 2010s (a) and
 668 its changes between G4 and 2010s (b, e), between RCP4.5 and 2010s (c, f) and between RCP8.5
 669 and 2010s (d, g) in Beijing-Tianjin province based on the ISIMIP and WRF results, respectively.
 670 PM_{2.5} concentration is based on the “baseline” emissions under G4, RCP4,5 and RCP8.5 in the
 671 middle 3 figures (b-d), and it is based on the “mitigation” emissions under G4, RCP4,5 and RCP8.5
 672 in the bottom 3 figures (e-g).

673

674 4. Discussion

675 4.1 Apparent temperature

676

677 Both ISIMIP and WRF can reproduce the observed (CN05.1) spatial patterns and
 678 seasonal variabilities of apparent temperature in the region around Beijing. WRF shows
 679 warm biases in AP during all months relative to CN05.1 due to warmer temperatures in

680 urban areas, with the exception of BNU-ESM and HadGEM2-ES driven summers (Fig.
681 S8). Both ISIMIP and WRF tend to overestimate population weighted NdAP_32 by
682 370% and 590%, respectively. These large discrepancies are due to relatively small
683 overestimates of the likelihood of the tails of the probability distributions which leads
684 to a dramatic increase in the frequency of extreme climate events (Dimri et al., 2018;
685 Huang et al., 2021). AP is about 1.5°C warmer than 2 m temperature over the Beijing
686 and Tianjin urban areas in summer due to higher vapor pressures amplifying warmer
687 urban temperatures, and this is despite humidity being lower over the cities. Under high
688 humidity conditions, a slight increase in temperature will cause a large increase in heat
689 stress (Li et al., 2018; Luo and Lau, 2019). AP is nearly 4°C colder than 2 m temperature
690 in winter due to wind speed (Fig. 2d). Differences between AP and 2 m temperature
691 (AP-T) during summer are greater in urban areas than neighboring rural areas.

692

693 The apparent temperatures in Beijing Tianjin urban areas under G4 in the 2060s are
694 simulated to be 1°C and 2.5°C lower than RCP4.5 and RCP8.5, although AP would be
695 higher than in the recent past. The cooling effect of G4 relative to RCP4.5 and RCP8.5
696 is greatest under HadGEM2-ES (Fig. S9, S10), due to the ESM having largest
697 temperature differences between scenarios (Wang et al., 2022). WRF downscaling
698 produces reduced seasonality in AP compared with ISIMIP, and WRF produces
699 relatively cooler summers and warmer winters than ISIMIP, and so much less
700 differences in apparent temperature ranges (Fig. 15). Differences in AP between G4 and
701 the RCP scenarios are mainly driven by temperature. In all scenarios and downscalings
702 AP rises faster than the temperature due to decreased wind speeds in the future (Li et
703 al., 2018; Zhu et al., 2021) but mainly because of rises in vapor pressure driven by
704 rising temperatures. This effect occurs despite the general drying expected under solar
705 geoengineering (Bala et al., 2008; Yu et al., 2015).

706

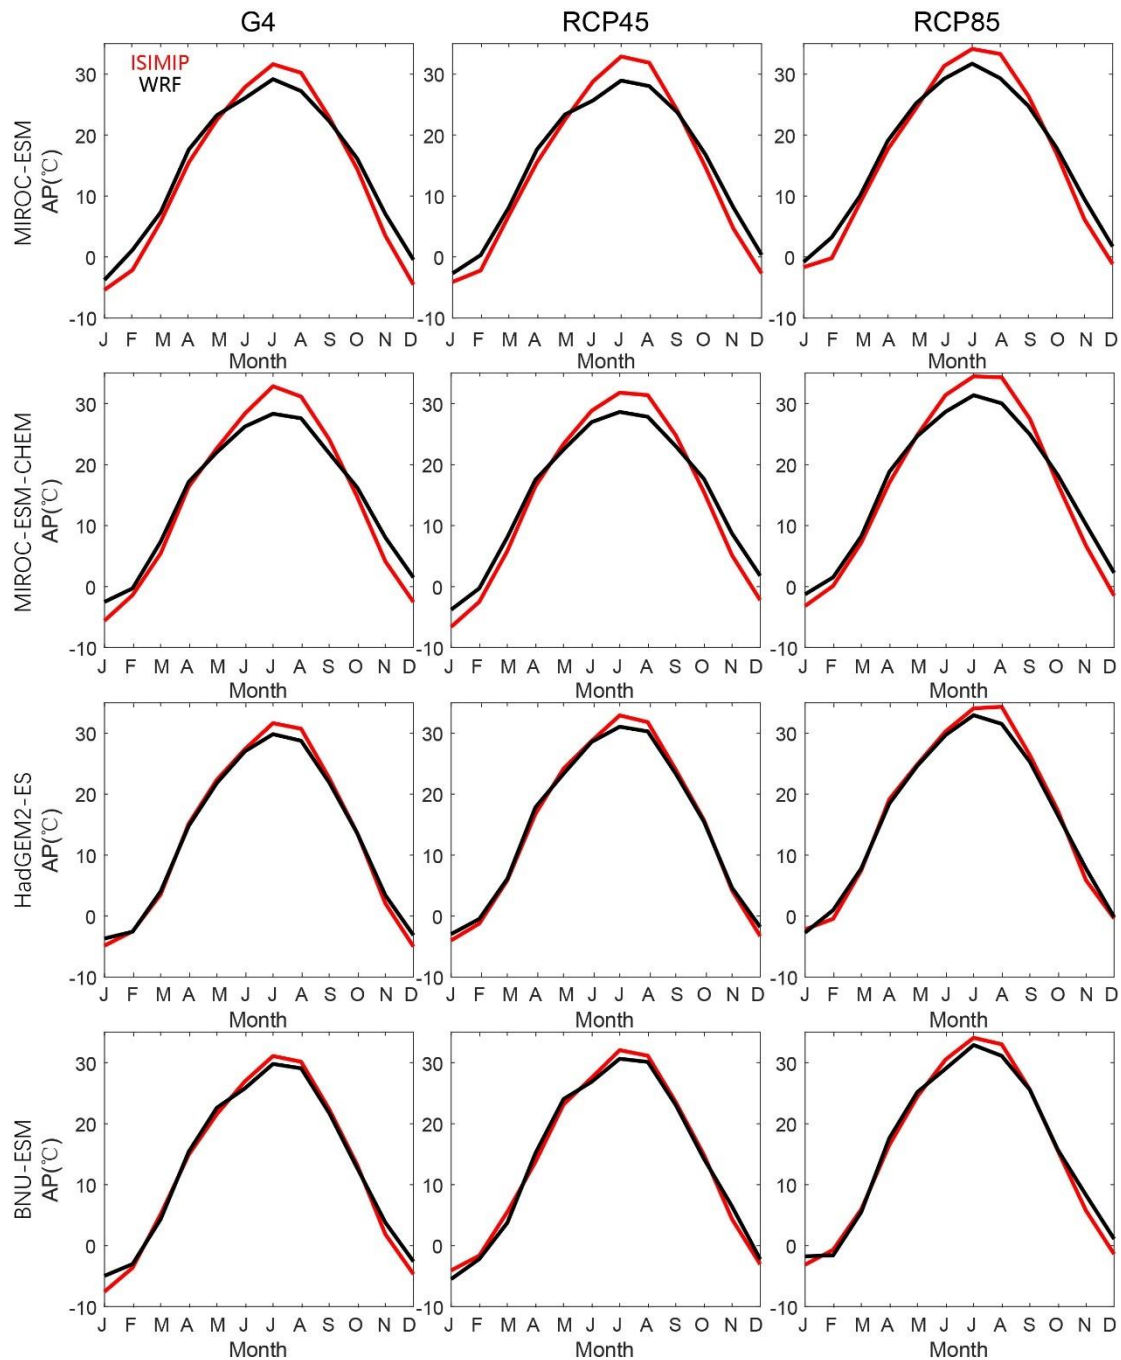

707 The NdAP_32 under G4 is projected to decrease by 8.6 days per year by ISIMIP and
708 6.3 days per year by WRF relative to RCP4.5 for Beijing-Tianjin Province. Much larger
709 reductions in NdAP_32 of 33.5 days per year (ISIMIP) and 19.6 days per year (WRF)
710 are projected relative to RCP8.5. Differences between scenarios in frequency of
711 dangerously hot days are far larger using ISIMIP statistical downscaling than using
712 WRF. This is another impact of the reduced seasonality of WRF compared with ISIMIP
713 (Fig. 15).

714

715 The higher resolution WRF simulation produces a much larger range of apparent
716 temperatures across the domain than CN05.1 and ISIMIP downscaling. This increased
717 variability makes reaching a statistical significance threshold more challenging for
718 WRF than ISIMIP results. Despite this, the ESM-driven differences in WRF output are
719 less than from ISIMIP, reflecting the physically based processes in the dynamic WRF
720 simulation. This reduces the impact of differences in ESM forcing at the domain
721 boundaries with WRF compared with the statistical bias correction and downscaling
722 methods. Although there are some uncertainties between models and downscaling
723 methods, G4 SAI can not only reduce the mean apparent temperature but also decrease

724 the probability of PDF tails (extreme events) in summer.

725

726

727 **Figure 15.** Seasonal cycles of apparent temperature from MIROC-ESM, MIROC-ESM-CHEM,
728 HadGEM2-ES and BNU-ESM under G4, RCP4.5 and RCP8.5 in Beijing-Tianjin urban areas during
729 2060s based on ISIMIP (red) and WRF (black) methods.

730

731 4.2 PM_{2.5}

732 We established a set spatially gridded MLR models based on the 4 ESMs downscaled
733 variables under ISIMIP and WRF. The meteorological factors impact PM_{2.5} in complex
734 ways, but the simple spatially gridded MLR models display enough skill to make some

735 illustrative projections of future PM_{2.5} explaining about 70% of the variance during the
736 historical period. PM_{2.5} concentration is correlated with emissions and anti-correlated
737 with temperature in most parts of the domain (Fig, S19-S20). Increased turbulence
738 increases diffusion of PM_{2.5} (Yang et al., 2016), and higher temperatures increase
739 evaporation losses (Liu et al., 2015) of ammonium nitrate (Chuang et al., 2017), and
740 other components (Wang et al., 2006). Humidity may have both positive and negative
741 effects on PM_{2.5} (Chen et al., 2020). It causes more water vapor to adhere to the surface
742 of PM_{2.5}, thereby increasing its mass concentration and facilitating aerosol growth
743 (Cheng et al., 2017; Liao et al., 2017). However, when the humidity exceeds a certain
744 threshold, coagulation and particle mass increases rapidly, promoting deposition (Li et
745 al., 2015). So, the slope coefficients between PM_{2.5} and humidity are positive in low
746 humidity areas, including southern plain and the Beijing-Tianjin province, but negative
747 in some northern mountain areas (Fig. S19, S20).

748

749 There are large spatial differences in wind speed and direction impacts on PM_{2.5}. Yang
750 et al. (2016) found that weaker northerly and westerly winds tend to increase the PM_{2.5}
751 concentration in northern and eastern China, respectively. The effects of wind direction
752 depend on the distribution of emitted PM_{2.5} and the condition of the underlying surface
753 (Chen et al., 2020). Most sources of PM_{2.5} lie to the south of our domain, relatively
754 clean conditions prevail to the north, so northerly winds tend to advect clean air, while
755 southerlies bring high concentrations of aerosols. Weak winds tend to increase PM_{2.5}
756 and smog formation due to sinking air and weak diffusion (Su et al., 2017; Yang et al.,
757 2017).

758

759 Emissions reductions are expected to play the dominant role in the decrease of PM_{2.5}
760 concentrations under G4 aerosol “mitigation” in 2060s (Fig. 12). Meteorological
761 changes under the different future scenarios make much smaller changes as evidenced
762 by the scenarios using “baseline” – that is present day PM_{2.5} emissions, with decreases
763 in mean annual concentration of 1.0 (1.3), 1.8 (2.0), 3.3 (3.2) $\mu\text{g}/\text{m}^3$ over Beijing-
764 Tianjin province under G4, RCP4.5 and RCP8.5 with WRF (ISIMIP), (Table S2), which
765 are mainly caused by the temperature increases (Fig. 13). The negative relationships
766 between emission and PM_{2.5} concentration result in the increase of PM_{2.5} under G4
767 (“mitigation”) relative to 2010s in the north of Beijing with WRF. This may be due to
768 changes in PM_{2.5} out of the domain being opposite to those in domain during the MLR
769 fitting period, since relocation of polluting sources from the urban areas mainly to the
770 west, was occurring over the calibration period. The accuracy of PM_{2.5} emission data is
771 also crucial for training MLR models, and PM_{2.5} data was sparse before 2013, relying
772 on reconstructions based on satellite optical depth estimates. Although both increase of
773 temperature and decrease of emission explain more than 90% of the decrease in PM_{2.5}
774 in most areas, there are large spatial differences due to wind and humidity. On the one
775 hand, there is uncertainty in the differences in changes of wind speed and humidity
776 between different ESMS and downscaling methods; on the other hand, the complex

777 physical relationship between them and PM_{2.5} also increases uncertainties. Reductions
778 in PM_{2.5} in the future are projected to decrease PM_{2.5} related health issues, although its
779 effect on different diseases are different. Changes in PM_{2.5} related risk between G4 and
780 RCPs are from 1-3%, with PM_{2.5} emissions policy dominating differences over climate
781 scenario.

782

783 Eastham et al. (2018) deduced from experiments using 1 Tg/yr SAI in a coupled
784 chemistry-transport model directly simulating atmospheric chemistry, transport,
785 radiative transfer of UV, emissions, and loss processes, that per unit mass emitted,
786 surface-level emissions of sulfate result in 25 times greater population exposure to
787 PM_{2.5} than emitting the same aerosol into the stratosphere. The G4 experiment specifies
788 5 Tg/yr injection rate, which over our domain would equate to 1450 t/yr if it was
789 deposited uniformly globally (which it certainly would not be). Reducing this by the
790 1/25 factor amounts to 58 t/yr which can be compared with present PM_{2.5} emissions of
791 around 3.3×10^5 t/year in our domain. If we consider the aerosol deposition under G4
792 scenarios, PM_{2.5} concentration will be 0-1 $\mu\text{g}/\text{m}^3$ higher than that without due to
793 deposition of the SAI aerosols (Fig. S21), and RR is projected to increase by 0.01% for
794 Beijing-Tianjin province (Table S3). This comparison suggests that tropospheric
795 emissions will be much more important for human health in our domain than from the
796 SAI specified by G4.

797

798 The most important change in PM_{2.5} will come from emissions reductions, with the
799 different weather conditions under both G4 and RCP scenarios making relatively little
800 practical differences in concentrations. PM_{2.5} concentration is expected to decrease
801 significantly (ISIMIP: $-6.5 \mu\text{g}/\text{m}^3$, WRF: $-4.3 \mu\text{g}/\text{m}^3$) in the Beijing-Tianjin province,
802 but they will still not meet either Chinese or international standards. The temperature
803 under G4 is lower than that under RCP4.5 and RCP8.5 scenarios, which makes the
804 PM_{2.5} concentration under G4 higher. But the difference in PM_{2.5} between the two is
805 small and even within uncertainty due to projected differences in humidity and wind.
806 Potentially improved estimates from more complex models such as WRF-Chem,
807 CMAQ and GEOS-Chem over the simple MLR methods used here will be of limited
808 value unless the differences between the ESM driving these models is reduced. It can
809 be confirmed that emission policies based on the 13th Five Year Plan are not enough,
810 and higher emission standards need to be developed for a healthy living environment.

811

812 **5. Conclusion**

813 Our study on thermal comfort and aerosol pollution under geoengineering scenarios for
814 the Beijing megalopolis may be useful across the developing world, which is expected
815 to suffer disproportionate climate impact damages relative the global mean, while also
816 undergoing rapid urbanization. Assessing health impacts and mortality due to heat

817 stress and PM_{2.5} under greenhouse gas scenarios should consider urbanization and the
818 change to concrete surfaces from vegetation that leads to differences in heat capacities,
819 rates of evapotranspiration, and hence humidity and apparent temperature. These
820 require downscaled analyses, accurate meteorological and high-resolution land surface
821 datasets, and industrial development scenarios.

822

823 In our analysis we assumed the urban area did not change over time, and also that
824 population remains distributed as in the recent past. This may be reasonable in the
825 highly developed and relatively mature greater Beijing-Tianjin region but should be
826 considered in rapidly urbanizing regions elsewhere. There certainly will be changes
827 over time in the radiative cooling from surface pollution sources. PM_{2.5} is a health issue
828 in many developing regions (Ran et al., 2023), but as wealth increases efforts to curb
829 air pollution generally clean the air. This has clear health benefits, but also removes
830 aerosols from the troposphere that cool the surface. The urban areas that have higher
831 apparent temperatures at present are also the areas with greatest aerosol load and hence
832 greatest cooling. Once that is removed direct radiation, air temperatures and apparent
833 temperatures will all rise – by several degrees (Wang et al., 2016). So, a future more
834 comprehensive health impact study would include both the negative health impacts of
835 aerosol pollution and the potential cooling effects those aerosols produce. Additionally,
836 the formulation of apparent temperature used does not consider the effect of radiation
837 on human comfort (Kong and Huber, 2022). When PM_{2.5} levels are high there is no
838 shade because the sky is milky-white, similarly SAI will brighten the sky (Kravitz et
839 al., 2012). Comfort is increased in clear sky conditions when shade is readily found.

840

841 The changes simulated to relative risk from increased PM_{2.5} under the G4 SAI scenario
842 are about 1-3% worse than under RCP4.5, mainly because of lower temperatures under
843 G4. The difference this would make to the overall health burden under SAI depends on
844 the range of other impacts that include changes in apparent temperature we discuss. G4
845 reduces the number of days with AP>32 (when extreme caution is advised) by 6-8 per
846 year relative to RCP4.5 and by 20-34 relative to RCP8.5. But G4 itself will still increase
847 these extreme caution days by 1-20 relative to conditions in the 2010s. Lowering PM_{2.5}
848 emissions will increase ground temperatures and the associated risk of dangerous
849 apparent temperatures will also increase rapidly as the distribution of temperatures is
850 shifted making presently rare hot events into much more frequent heat waves.

851

852 **Code and data availability**

853 All ESGM data used in this work are available from the Earth System Grid Federation
854 (WCRP, 2021; <https://esgf-node.llnl.gov/projects/cmip6>, last access: 14 July 2021).
855 The WRF and ISIMIP bias-corrected and downscaled results are available for the
856 authors on request. WRF and ISIMIP codes are freely available at the references cited
857 in the methods sections.

858 **Supplement link**

859 The link to the supplement will be included by Copernicus.

860 **Author contribution**

861 JCM and LZ designed the experiments, JW performed the simulations. All the authors
862 wrote the manuscript.
